Abstract

In this study, the effects of addition of the antioxidant ascorbic acid (AsA) were evaluated during porcine in vitro embryo production (IVP) and vitrification. In experiment 1, the effects of AsA supplementation during IVM, IVF and IVC were evaluated, using a total of 2,744 oocytes in six replicates. The IVM, IVF and embryo IVC media were supplemented or not (control) with 50 μg/mL AsA in all possible combinations. No significant effects of AsA were detected in any of the maturation, fertilization or embryo development parameters assessed. In experiment 2, we evaluated the effects of adding AsA to vitrification-warming media on the post-warming survival and quality of blastocysts. Day-6 in vitro-produced blastocysts (N=588) from six replicates were randomly divided in two groups, with vitrification and warming media either supplemented with 50 μg/mL AsA (VW+ group) or un-supplemented (VW- control). Addition of AsA increased (P<0.05) blastocyst survival rate after vitrification compared with that of VW- control embryos. Vitrification and warming increased (P<0.05) the production of oxygen species (ROS) and reduced (P<0.05) the glutathione levels in blastocysts. Although VW+ blastocysts displayed higher (P<0.05) ROS levels than those of fresh control blastocysts, the levels were lower (P<0.05) than those found in VW- control blastocysts. In conclusion, under the experimental conditions, supplementation of IVM/IVF/IVC media with AsA did not improve the embryo production in vitro. By contrast, the addition of AsA to chemically defined vitrification and warming media increased the survival of in vitro-produced porcine blastocysts by decreasing ROS production.

Keywords: Ascorbic acid; porcine; in vitro maturation; in vitro fertilization; vitrification.
1. Introduction

In vitro production (IVP) of porcine embryos is an important tool for agricultural, biotechnological and biomedical purposes. Although substantial progress has been achieved in embryo IVP systems [1,2,3], the overall efficiency remains unsatisfactory because of the prevailing high incidence of polyspermy during IVF [4-7], leading to low efficiency of blastocyst production and to poor quality of the resulting blastocysts [8,9]. Although many different supplements, such as follicular fluid [10], vitamins [11,12], growth factors [9] or hormones [13], have been added to IVP media in attempts to improve the IVP of porcine embryos, the general assumption is that IVC conditions remain suboptimal. One of the primary differences between in vitro and in vivo conditions is related to oxidative stress [14]. The oxygen content of IVP environments is higher than that in vivo, which results in increased production of ROS [15,16]. These high ROS levels during embryo IVP are harmful to gametes and embryos [17-19]. Thus, protecting oocytes and embryos against oxidative stress during in vitro culturing is a key step for improving embryo IVP efficiency and embryo quality. To achieve this goal, a widely used strategy is the addition of antioxidants to the media [12,20-23].

Ascorbic acid (AsA), the most important antioxidant in extracellular fluids [24], is one of the antioxidants tested in embryo IVP that shows some beneficial properties. When present during IVC, AsA increases the cleavage rate in bovine [25] and blastocyst rates in ovine [26]. In porcine, AsA shows positive effects on oocyte nuclear maturation [12] and blastocyst formation after parthenogenetic activation [27]. Addition of AsA also apparently protects embryos against oxidative stress during IVC, improving embryo developmental competence after either IVF [28] or parthenogenesis [27,29]. In some studies, the quality of blastocysts in terms of cell numbers [29] or survival after vitrification [30] also increases with supplementation with AsA during IVC. Moreover,
addition of AsA to vitrification and warming media supplemented with serum increases embryo survival rates of in vitro-produced porcine blastocysts [30]. Collectively, the above studies suggest that AsA could be an interesting molecule to use during embryo IVP and/or vitrification in porcine to avoid the excessive increase of ROS and their deleterious effects on oocytes and embryos. However, no systematic study has explored the influence of AsA on each step of the embryo IVP system and the presence of possible synergistic effects. Therefore, the aims of the present study were the following: (1) evaluate the effects of AsA supplementation to IVM, IVF and IVC media, including all possible combinations, on maturation, fertilization and embryonic developmental parameters; and (2) assess the effects of adding AsA to vitrification and warming defined media on the vitrification survival of IVP-porcine blastocysts.

2. Materials and methods

All experimental procedures used in this study were performed in accordance with the 2010/63/EU EEC Directive for animal experiments and were reviewed and approved by the Ethical Committee for Experimentation with Animals of the University of Murcia, Spain (research code: 1002/2012).

2.1. Reagents and culture media

Unless otherwise specified, all chemicals used in this study were purchased from Sigma–Aldrich Co. (Alcobendas, Madrid, Spain). A physiological saline solution composed of NaCl 0.9% (w/v) and 70 μg/mL kanamycin was used to transport ovaries from the slaughterhouse to the laboratory. The cumulus–oocyte complexes (COCs) were collected and washed in Tyrode’s lactate supplemented with 10-mM HEPES and 0.1% (w:v) polyvinyl alcohol (TL-PVA) [31,32]. The oocyte maturation medium was
TCM-199 (Gibco Life Technologies S.A., Barcelona, Spain) supplemented with 0.57-mM cysteine, 0.1% (w:v) PVA, 10 ng/mL EGF, 75 μg/mL penicillin G potassium, and 50 μg/mL streptomycin sulfate. The basic medium used for IVF was a modified Tris-buffered medium [33] enriched with 2.0-mM caffeine and 0.2% (w:v) BSA. A Dulbecco’s PBS (Gibco, Grand Island, NY) with 4 mg/mL of BSA was used for washing spermatozoa after thawing and before re-suspension in IVF medium. The embryo culture medium was North Carolina State University 23 (NCSU23) [34] supplemented with 0.4% BSA. The basic medium for vitrification and warming was the chemically defined TL-PVA medium. The first vitrification medium (V1) was TL-PVA containing 7.5% (v:v) of ethylene glycol and 7.5% of dimethyl sulfoxide (DMSO), and the second vitrification medium (V2) was TL-PVA containing 16% (v:v) of ethylene glycol and 16% DMSO and 0.4 M sucrose. The warming medium consisted of TL-PVA supplemented with 0.13 M sucrose.

2.2. Cumulus-oocyte complexes (COCs) collection and in vitro maturation

Ovaries were collected from pre-pubertal gilts at a local slaughterhouse and transported to the laboratory at the University of Murcia at 35 °C within 1 h of collection. Then, medium-sized follicles (3–6 mm in diameter) were sectioned with a sterile scalpel blade into TL-PVA to collect COCs. Oocytes surrounded by two or more layers of compact cumulus cells and with evenly granulated cytoplasm were selected and washed in maturation medium. Groups of 75-80 COCs were transferred into a well of a four-well multidish (Nunc, Roskilde, Denmark) containing 500 μL of maturation medium supplemented with 10 IU/mL eCG (Folligon; Intervet International B.V., Boxmeer, The Netherlands) and 10 IU/mL hCG (Veterin corion; Divasa Farmavic S.A., Barcelona, Spain) for 22 h. The oocytes were then incubated for another 20 to 22 h in maturation
medium without hormones. Maturation was performed under mineral oil at 38.5 °C in
5% CO₂ in air and 95% to 97% relative humidity.

2.3. In vitro fertilization

After oocyte maturation, cumulus cells were removed with 0.1% hyaluronidase in
maturation medium by vortexing for 2 min at 1,660 rounds/min. The denuded oocytes
were washed three times in IVM medium and three times in IVF medium. Then, groups
of 30 oocytes were placed into 50 μL drops in IVF medium in a 35 mm × 10 mm Petri
dish (Falcon; Becton Dickinson Labware, Franklin Lakes, NJ, USA) under mineral oil
and were maintained in an incubator (38.5 °C, 5% CO₂ in air and 95% to 97% relative
humidity) until addition of spermatozoa. Semen from a mature boar cryopreserved in
0.5 mL straws as described by Roca et al. [35] was thawed (two straws per replicate) in
a circulating water bath at 37 °C for 20 s. Immediately after thawing, 100 μL of semen
was washed three times by centrifugation at ×1,900 g for 3 min in 10 mL of Dulbecco’s
PBS. The resulting pellet was suspended in IVF medium. After appropriate extension,
50 μL of this sperm suspension was added to the medium with the oocytes such that the
final sperm concentration was 3 × 10⁵ spermatozoa/mL; thus, each oocyte was exposed
to 1,000 spermatozoa. Oocytes were co-incubated with spermatozoa for 5 h under
mineral oil at 38.5 °C in an atmosphere of 5% CO₂ in air and 95% to 97% relative
humidity.

2.4. In vitro culture and assessment of embryonic development

After gamete co-incubation, presumptive zygotes were washed by three rounds of
mechanical pipetting in IVC medium to remove spermatozoa that were not bound to the
zona pellucida. Presumptive zygotes were then transferred (30 zygotes per well) into a
four-well multidish containing 500 μL of glucose-free embryo culture medium
(NCSU23-BSA) supplemented with 0.3-mM pyruvate and 4.5-mM lactate for 2 days
and then changed to fresh embryo culture medium containing 5.5-mM glucose for an
additional 5 day period. Embryo culture was performed under paraffin oil in an
incubator at 38.5 °C, 5% CO2 in air, and 95% to 97% relative humidity.

2.5. Assessment of maturation, fertilization and embryo development
To evaluate the maturation and fertilization, representative aliquots of oocytes and
presumptive zygotes were fixed at 44 h of IVM and at 18 h after IVF, respectively, in a
solution of acetic acid:ethanol (1:3) for 72 h at room temperature. Fixed oocytes and
presumptive zygotes were stained with 1% (w:v) lacmoid in 45% acetic acid and
examined under a phase-contrast microscope at magnification ×400. Oocytes with
chromatin enclosed in a nuclear membrane or those with condensed chromatin but
without extruded polar body were classified as immature oocytes. Oocytes were
considered mature when their chromosomes were organized at metaphase and they
showed an extruded first polar body (MII).

Presumptive zygotes were considered penetrated when they contained one or more
swollen sperm heads and/or male pronuclei and two polar bodies. Sperm penetration
rate was the ratio of the number of penetrated oocytes relative to the total number of
mature oocytes inseminated. Monospermic rate was calculated as the ratio of oocytes
with one female pronucleus, one male pronucleus and two polar bodies to the total
number of matured oocytes penetrated. The efficiency of fertilization was the ratio of
the number of monospermic oocytes relative to the total number of matured oocytes
inseminated.
The cleavage (ratio of the number of embryos cleaved to two to four cells of the total number of oocytes inseminated) and blastocyst formation rates (ratio of the number of blastocysts of the total number of cleaved embryos) were morphologically evaluated using a stereomicroscope at Day 2 and Day 7 post-insemination (Day 0), respectively. The total efficiency was described as the percentage of the total number of inseminated oocytes that reached the blastocyst stage. Blastocysts were fixed in 4% (v:v) paraformaldehyde in PBS for 30 min at room temperature (24 °C) to assess total cell numbers. After fixation, embryos were washed with PBS containing 3 mg/mL BSA (PBS-BSA), placed on a slide in a drop of 4 μL of VECTASHIELD (Vector Labs, Burlingame, CA, USA) containing 10 μg/mL Hoechst 33342, and covered with a coverslip. Stained embryos were examined with fluorescence microscopy using a 330 to 380-nm excitation filter. The total number of nuclei that showed blue fluorescence was counted.

2.6. Vitrification and warming; assessment of survival and hatching rates

Vitrification was performed according to the method described previously [36,37]. All media used for vitrification and warming were held at 38.5 °C. Briefly, groups of five to six embryos were washed twice in TL-PVA and consecutively equilibrated in V1 for 3 min and in V2 for 1 min for vitrification. During the final equilibration, embryos were placed in a 1 μL drop and loaded in the narrow end of a super open pulled straw (SOPS; Minitüb, Tiefenbach, Germany) by capillary action. Subsequently, straws containing the embryos were horizontally plunged into liquid nitrogen (LN₂). After storage in LN₂ for one week, the straws were removed and warmed by the one-step warming method [38,39]. Briefly, the straws were vertically submerged in one well of a four-well multidish containing 800 μL of warming medium and equilibrated for 5 min. Then,
vitrified-warmed blastocysts were washed in TL-PVA and cultured in vitro to assess the
embryo viability. Vitrified-warmed blastocysts that reformed their blastocoelic cavities
after warming and displayed a normal or thinning zona pellucida with an excellent or
good appearance during the culture were considered viable. The survival rate was
defined as the ratio of viable embryos to the total number of vitrified-warmed cultured
blastocysts. Additionally, after warming, the hatching rate (ratio of hatching or hatched
embryos at the end of the culture to the total number of cultured embryos) was
evaluated.

2.7. Differential staining

The number of inner cell mass (ICM) and trophectoderm (TE) cells of the vitrified-
warmed blastocysts was determined using an indirect immunofluorescence protocol
[39]. Blastocysts were fixed with paraformaldehyde as described before for total cell
evaluation. Fixed embryos were permeabilized (1.5% Triton X-100 and 0.15% Tween
20 in PBS) at 4 °C overnight. Permeabilized blastocysts were incubated at room
temperature first in a 2 N HCL solution for 20 min and then in 100 mM Tris-HCl (pH
8.5) for 10 min. After denaturation and washing (3 times for 2 min in PBS-BSA),
blastocysts were incubated for 6 h in blocking solution (PBS containing 1% BSA, 10%
Normal Donkey Serum and 0.005% Tween 20) at 4 °C. After washing (3 times for 2
min in PBS-BSA), blastocysts were incubated with the primary CDX-2 antibody (1:200
in the commercial dilution solution; BioGenex, San Ramon, CA, USA) for 1.5 days.
Then, blastocysts were washed (3 times for 2 min in PBS-BSA) and incubated with
donkey anti-mouse IgG-Alexa Fluor® 568 conjugate (1:1000 in blocking solution;
Invitrogen, Rockford, USA). Finally, blastocysts were washed twice for 15 min in PBS-
BSA, placed on a slide in 4 μL of Vectashield (Vector Labs, Burlingame, CA, USA)
containing 10 μg/mL Hoechst 33342, and covered with a coverslip. Stained blastocysts were examined with a fluorescence microscope using an excitation wavelength of 330- to 380-nm to count the total number of nuclei stained with Hoechst and a 536 nm excitation filter to count trophectoderm cells that were stained with Alexa Fluor 568 showing red fluorescence.

2.8. Measurement of intracellular GSH and ROS levels

Intracellular GSH and ROS levels of embryos were determined by staining with CellTracker Blue (4-chloromethyl-6.8-difluoro-7-hydroxycoumarin; CMF2HC; Invitrogen, ThermoFisher scientific, Massachusetts, USA) and H2DCFDA (2’, 7’-dichlorodihydrofluorescein diacetate; Invitrogen), respectively. Blastocysts were washed in TL-PVA and incubated in the dark for 30 min in TL-PVA medium containing 10 μM CellTracker Blue and 10 μM H2DCFDA at 38.5 °C. Stained embryos were washed three times in TL-PVA. Then, groups of 5 embryos were transferred into 10-μL droplets of TL-PVA medium, and the fluorescence was immediately observed with fluorescence microscopy with UV filters (370 nm for GSH and 460 nm for ROS). Fluorescence emissions were recorded as TIFF files using a digital camera connected to the fluorescent microscope. The fluorescence intensities of each blastocyst were analyzed by ImageJ software (Version 1.51h; National Institutes of Health, Bethesda, MD, USA).

2.9. Experimental design

2.9.1. Experiment 1
In the first experiment, the effects of AsA supplementation in IVM, IVF and IVC media on maturation, fertilization and embryo development were evaluated. For the evaluation, oocyte maturation, fertilization, and embryo culture were performed in the presence or absence of 50 μg/mL AsA in all possible combinations, which involved a total of 8 experimental groups. A total of 2,744 oocytes were used in six replicates. A random subset of oocytes (N=149) and presumed zygotes (N=1,142) from each group was fixed and stained at 44 h of IVM and at 18 h after IVF to evaluate the maturation and fertilization parameters, respectively. The remaining presumptive zygotes (N=1,602) were cultured to assess in vitro embryo development. Day 7 blastocysts were fixed and stained to assess their total cell number.

2.9.2. Experiment 2

In the second experiment, the effect of adding AsA to vitrification-warming media on the post-warming survival and quality of in vitro-produced porcine blastocysts was evaluated. The IVP of blastocysts was performed without AsA. This experiment was performed in a total of six replicates. Day-6 in IVP full-expanded blastocysts (N=588), morphologically classified as excellent or good, were randomly divided into one of two groups in which vitrification and warming media were supplemented with 50 μg/mL AsA (VW+ group) or not supplemented (VW- control). This AsA concentration was selected based on previous experiments (Kere et al., 2013). After warming, VW+ (N=281) and VW- control (N=307) blastocysts were cultured in vitro for 24 h to assess the embryo survival and hatching rates. A random subset (N=21) of vitrified-warmed blastocysts classified as viable from each group were subjected to differential staining to assess the total number of cells, the number of cells in the inner cell mass (ICM) and the number of cells in the trophectoderm (TE). Finally, the intracellular GSH and ROS
levels from VW+, VW- control and some fresh in vitro-produced blastocysts (Fresh control) were measured.

2.10. Statistical analyses
Statistical analysis was performed using the IBM SPSS 19 statistical software package (SPSS, Chicago, IL, USA). Continuous variables are expressed as the mean ±SD. Binary variables (maturation, penetration, monospermy, cleavage, blastocyst formation, efficiency, survival and hatching rates) were obtained by calculating the percentage in every well of each experimental group and in each of the replicates. These data are expressed as the mean ± standard deviation (SD). The Kolmogorov-Smirnov test was used to test for normally distributed data. Means of more than two groups were compared using a mixed-model analysis of variance (ANOVA), followed by the Bonferroni post hoc test. Pairwise comparisons of means were performed using Student’s t-test. Differences were considered significant at P<0.05.

3. Results

3.1. Experiment 1.
Effects of AsA supplementation on IVM, fertilization and embryo development.
The addition of AsA had no effect on the percentage of MII oocytes at 44 h of maturation between treatment (81.4%) and control (83.5%). Supplementation of IVM, IVF and IVC media also had no effect on any fertilization parameter (Table 1). Rate of sperm penetration was close to 70% with monospermy approximately 60% in all groups. The overall IVF efficiency of the IVP system ranged from 37.6±8.5% to 47.3±13.9% with no differences between treatment and control groups.
The embryonic development parameters are presented in Table 2. Addition of AsA did not affect the development to the 2-4 cell stage or blastocyst formation at the end of the culture period. The total efficiency of blastocyst production was always approximately 30%. The quality of the in vitro-produced blastocysts in terms of total cell number (range from 44.1±20.4 to 53.0±26.2 cells) did not vary with AsA supplementation.

3.2. Experiment 2

Effects of AsA supplementation to vitrification and warming media on blastocyst survival, hatching rate and embryo quality.

The addition of AsA during vitrification and warming increased (P<0.05) blastocyst survival rate compared with that of VW- control embryos (Table 3). However, the blastocysts survival and hatched rates 24 h after warming were not affected by AsA addition. Total cell numbers and the distribution of cells between the TP and the ICM (Table 4) were also comparable between the two vitrification groups.

The vitrification and warming procedures increased (P<0.05) intracellular ROS and decreased (P<0.05) GSH levels, compared with those of the controls (Fig. 1). Addition of AsA to the vitrification-warming media decreased (P<0.05) ROS production but did not affect GSH. Those embryos vitrified and warmed without AsA (VW- control) displayed the highest (P<0.05) intracellular ROS values, whereas those treated with AsA had intermediate ROS levels.

4. Discussion

In the present study, the effects of AsA treatment were assessed during porcine IVM, IVF and/or IVC on variables of maturation, fertilization and embryonic development. Despite previous reports of some positive effects of exogenous antioxidants within IVP,
the present study showed that the supplementation of media with AsA did not improve
the overall efficiency of our IVP system. However, AsA had a clear beneficial effect
during vitrification and warming, increasing the vitrification survival of in vitro-
produced blastocysts.

In the current study, AsA supplementation to oocyte IVM medium did not significantly
affect the maturation or fertilization rates or the subsequent embryo development after
IVF. These results are consistent with previous investigations in ovine [26], bovine [39]
and porcine [11], which did not demonstrate any effect of AsA supplementation during
IVM on the developmental competence of porcine oocytes and embryos. Some studies
report positive effects of AsA during maturation using parthenogenetically activated
[27] or denuded oocytes [12]. Kere et al. [27] observed an increase of the cleavage rate,
blastocyst formation and blastocyst total cell number after parthenogenetic activation of
porcine oocytes matured with AsA. The effect of AsA on parthenogenetically activated
oocytes could be due to the higher sensitivity of these oocytes to oxidative
environments than those oocytes subjected to IVF [40]. Consistent with this hypothesis,
Tao et al. [12] demonstrated improved nuclear maturation of porcine denuded oocytes
when AsA was added to the IVM medium. In this case, AsA during IVM was also
beneficial under an increased oxidative stress condition due to the absence of cumulus
cells surrounding the oocytes during IVM [41]. Together with our present results, these
previous observations suggest that AsA has a beneficial effect during maturation when
the generation of ROS is extremely high or protective mechanisms against oxidative
stress are lacking.

We believe this is the first study to evaluate the effects of the addition of AsA during
IVF of porcine oocytes. Previous studies on the effects of antioxidants during the IVF
period have reported contradictory results. With regard to IVF, it is important to note
that physiological levels of ROS are required to induce hyperactivation and capacitation of spermatozoa [42,20], both pre-requisites for fertilization. Although some antioxidants added to sperm before or during IVF have improved subsequent developmental capacity of bovine and ovine embryos [43], excess antioxidants impair fertilization, normal pronuclear formation and embryo development in bovine [44]. In our study, the supplementation of IVF media with AsA did not have any effect on the fertilization parameters or on the developmental competence of fertilized oocytes.

With respect to the embryo culture, the results followed the same pattern as those for IVM and IVF. Thus, the addition of AsA to the IVC medium did not alter the IVC parameters and did not affect the number of cells in the blastocysts. These observations are similar to those reported by Castillo-Martín et al. [30]; however, they are in contrast to Hossein et al. [28] who obtained increased blastocyst formation when the ICV medium was enriched with AsA. To understand these discrepancies, we should consider the overall efficiency of each IPV system. Thus, our total blastocyst production efficiency (30-35%) and that reported by Castillo-Martín et al. [30] (20%) are considered adequate for a porcine IVP system, and in these circumstances, AsA did not exert any effect. By contrast, under less efficient conditions in which the blastocyst formation rate was close to 9% [28], the addition of AsA was beneficial. A positive effect of AsA was also observed with embryos derived from parthenogenesis [27,29], which may be more sensitive to oxidative stress than IVF-derived embryos because of their biological differences [45]. It is possible that AsA only exerts positive effects under highly oxidant conditions in which the detrimental effects of ROS are exacerbated. Following this logic, the present study showed a positive effect of AsA during vitrification and warming using chemically defined media, and these results are consistent with those obtained by Castillo-Martín et al. [30] using a vitrification and
warming system based on supplementation with fetal serum and AsA. During vitrification and warming, embryos are subjected to important disturbances in the redox status due to an increase of ROS and/or a decrease in the GSH levels [30,46,47]. In this study, vitrification and warming increased, as expected, the oxidative stress altering intracellular GSH and ROS levels compared with those of fresh blastocysts. However, addition of AsA mitigated this high oxidative stress by reducing intracellular ROS production of blastocysts and increasing the embryo survival rate after warming. Supplementation of AsA to cryopreservation media of mouse and bovine embryos had also beneficial effects by reducing peroxidation and increasing cryotolerance [48,49]. These results indicate that the addition of AsA or other antioxidants during vitrification and warming could be an efficient strategy to reduce the oxidative stress related to this technology and therefore to improve embryo survival.

In conclusion, under our experimental conditions and within a highly efficient porcine in vitro embryo production system, the supplementation of IVM/IVF/IVC media with AsA at a concentration of 50 μg/mL failed to further increase the IVP-outcomes. By contrast, the addition of AsA to chemically defined vitrification and warming media increased the vitrification survival by decreasing the ROS production. Thus, AsA supplementation is recommended for vitrification and particularly for unstable or low performing IVP systems.

</table>

Penetrated: Number of oocytes penetrated/total inseminated oocytes.
Monospermic: Number of oocytes with only one male pronucleus/total oocytes penetrated.
Efficiency: Number of monospermic oocytes/total oocytes inseminated.
Data are expressed as the mean ± SD (six replicates).
Table 2
Embryonic development achieved after oocyte maturation, fertilization and embryo culture with (+, 50 µg/mL) or without (-) ascorbic acid (AsA).

</table>

Cleavage: Number of 2,4-cell embryos/total inseminated oocytes cultured.
Blastocyst: Number of blastocysts/total cleaved embryos.
Total Efficiency: Number of blastocysts/total inseminated oocytes cultured.
Data are expressed as the mean ± SD (six replicates).
Table 3
Survival and hatching rates and quality (number and distribution of cells) after 24 h of culturing of Day 6 in vitro-produced porcine blastocysts vitrified-warmed in media supplemented with 50 µg/mL ascorbic acid (AsA; VW+) or without supplementation (VW- control).
