Statement of authorship

AE and AC designed the study. AC carried out the analyses and wrote the first draft of the manuscript. Both authors contributed substantially to revisions.

Data accessibility

Should the manuscript be accepted, supporting data will be archived in an appropriate public repository and the DOI will be included at the end of the article.

Keywords

body mass; feeding environment; trophic level; apparent competition; direct competition; food chain; indirect interactions

Abstract

Food webs and meso-scale motifs allow us to understand the structure of ecological communities and define species' roles within them. This species-level perspective on networks permits tests for relationships between species' traits and their patterns of direct and indirect interactions. Such relationships could allow us to predict food-web structure based on more easily-obtained trait information. Here we calculated the roles of species (as vectors of motif position frequencies) in six well-resolved marine food webs and identified the motif positions associated with the greatest variation in species' roles. We then tested whether the frequencies of these positions varied with species' traits. Despite the coarse-grained traits we used, our approach identified several strong associations between traits and motifs. Feeding environment was a key trait in our models and may shape species' roles by affecting encounter probabilities. Incorporating environment into future food web models may improve predictions of an unknown network structure.

Introduction

Understanding how species interact in ecological communities is a great challenge for ecologists, conservationists, and other stakeholders. Food webs –networks describing consumer-resource interactions– place species in their community context and can facilitate such endeavours. The food-web perspective is important because direct as well as indirect interactions between species can lead to responses to perturbations that are unpredictable when considering each species in isolation (Wootton, 1994; Schmitz, 1997). The occurrence of an interaction is influenced by species traits (Bartomeus *et al.*, 2016); traits are therefore likely to be valuable for predicting and understanding direct and indirect interactions between species (Woodward *et al.*, 2005; Pearse & Altermatt, 2013). If species’ traits are consistently related to their patterns of direct and indirect interactions (their food-web roles), then it may be possible to extrapolate the effects of species on their communities from their traits without knowing the full food web.

The first steps in this direction are food-web models based on predator-prey mass ratios (e.g., Woodward *et al.*, 2005; Brose *et al.*, 2006; Riede *et al.*, 2011), but body mass alone does not fully explain the structure of food webs (Zook *et al.*, 2011). Nevertheless, it has been shown that combinations of relatively few traits can predict a large part of the interactions (Eklöf *et al.*, 2013). In fact, less than 10 (and usually six or fewer) dimensions, where each dimension is a potential trait-axis in the multidimensional niche-space (Chase & Leibold, 2003), are needed to fully describe food-web structure (Eklöf *et al.*, 2013). This result suggests that a small number of traits is sufficient to predict each species’ feeding interactions although it still remains to be seen which traits have the most predictive power.

Here we are interested in relating species’ traits to their roles in networks rather than predicting the overall structure of a network. We define species’ roles based on their participation in meso-scale structures called “motifs” (Milo *et al.*, 2002; Alon, 2007; Stouffer *et al.*, 2012). These motifs are unique arrangements of n interacting species (Alon, 2007) and, for any given species, describe direct and indirect interactions with other species in the network. We focus on roles because they provide a species-level summary of a food web, unlike most commonly-reported measures of network structure (e.g., connectance) that summarise network structure (Dunne, 2006; Otto *et al.*, 2007) and therefore obscure most of the species-level details. Each motif contains one or more unique positions (e.g., the top, middle, or bottom species in a three-species chain; Fig. 1) specifying precisely which interactions each species contributes to the motif. These positions can be used to provide a higher level of detail when defining species’ roles. As it is reasonable to expect that species will be most strongly affected by species with which they interact or by species that directly interact with the focal species’ interaction partners (Jordán & Scheuring, 2002; Jordán *et al.*, 2006), we used three-species motifs as our units of analysis (Stouffer *et al.*, 2012; Cirtwill & Stouffer, 2015).

These three-species motifs can be considered the “building-blocks” of food webs (Milo *et al.*, 2002). Some motifs have clear ecological meanings (Bascompte & Melián, 2005). For example, the omnivory or intraguild predation motif (in which one resource is consumed by two predators, one of which also consumes the other predator) is believed to contribute to network stability by moderating non-equilibrium dynamics (McCann *et al.*, 1998). The three-species food chain motif, meanwhile, has been used to better understand trophic cascades (Hastings & Powell, 1991; Laws & Joern, 2013). Other motifs have not yet been

studied independently, but each unique arrangement of interacting species implies different consequences for the flow of energy and biomass through a food web and therefore provides information about how a focal species fits into its community (Cirtwill & Stouffer, 2015). Defining a species' role this way (i.e., as a vector of frequencies with which it appears in each position within each motif) provides a holistic summary of the way in which it is embedded in its food web. We can then explore how these species-level summaries may be related to species' traits. Here we use species' roles in six well-resolved marine food webs to identify broad traits that are strongly associated with variation in species' roles and may therefore be useful in future efforts to model network structure. We found that most of the traits we consider are related to at least one key position but that feeding environment is a particularly good candidate for inclusion in future food-web models.

Methods

Dataset

Food webs

To test which traits explain the most variation in species' structural roles, we used a set of 6 well-resolved marine food webs that include trait data for most species. The webs contain 92-488 species and 417-15 880 predator-prey interactions and describe communities ranging from Caribbean reefs to polar communities (Table S1, *Supplemental methods: food web details*). By covering such a broad range of communities, these webs allowed us to identify traits associated with network structure independent of local environmental variables.

Species traits

As well as predator-prey links, each web contained trait data. The traits we use in our analyses are such that they can be easily collected either from the literature or in the field when new data are assembled. The traits are body mass (g), trophic level, feeding environment, metabolic category, mobility, feeding type, and feeding mode (see *Supplemental methods: trait details* for details). Feeding type refers to the type of resources a species consumes while feeding mode refers to the way in which the species obtains these resources. Body mass and trophic level were measured as continuous variables while all other traits were treated categorically. These traits, which were selected based on ease of collection and applicability to the broadest possible range of species, are unlikely to be the only traits which influence the likelihood of an interaction between two species. A wide variety of traits affect foraging, vulnerability, and encounter probabilities (Gravel *et al.*, 2016). Due to this variety, the exact set of traits affecting any pair of species is unlikely to be known for most systems (Dormann *et al.*, 2017); we therefore focus on broad traits that are likely to affect many species in many systems.

Calculating species' roles

By “species' role” we refer to the pattern of direct and indirect interactions in which a species participates, within a food web. To describe species' roles, we began by decomposing each food web into its set of three-species motifs (Stouffer *et al.*, 2012; Cirtwill & Stouffer, 2015). Motifs are unique arrangements of species that describe direct and indirect interactions (Milo *et al.*, 2002). Each motif can be subdivided into 1-3 unique

positions (e.g., predators and prey in the direct competition motif; Fig. 1) in order to obtain a more detailed picture of the interaction pattern of a species. Over the set of 13 three-species motifs there are 30 unique positions. We can therefore define each species' role as a vector of the number of times the species appears in each of these positions. Note that each set of three interacting species is assigned to exactly one motif: that which includes all of the interactions among the triad. By extension, each species is assigned to only one position per triad of interacting species.

We were not interested in differences between roles due to some species being involved in more feeding links than others. We therefore normalised species' roles by dividing the count of each position by the total number of times the species appeared in any position. In some cases this would result in frequencies of zero which cannot be properly modelled using logistic regressions. To correct this, we added one to the count of each position for each species before dividing by the new total count across all species. Thus, all possible positions had non-zero frequencies in the roles of each species.

Roles and trophic groups

As well as the traits described above, we expect that roles will differ between species in different trophic or taxonomic groups. The effects of trophic groups (i.e., basal resources, intermediate consumers, and top predators) on species roles derive from the fact that basal resources and top predators can only occupy prey or predator positions, respectively. We therefore analysed species in different trophic groups separately. If a species had observed predators but no observed prey, it was classed as a basal resource. If a species had observed prey but no observed predators, it was classed as a top predator. Species with

both predators and prey were classed as intermediate consumers. Basal resources and top predators can appear in only six positions each while intermediate consumers can occupy any of the 30 positions; we defined the roles of each group based only on the positions that group could occupy.

Roles and taxonomic groups

Species in different taxonomic groups might also have different roles as these species are likely to have similar traits (e.g., physical or chemical defences, dentition, behaviour) which could influence their interactions as predators or prey. Grouping species based on high-level taxonomies provides an alternative approach to grouping species based on trophic groups. Importantly, taxonomy does not depend on the structure of the network and therefore can be used to group species where the network structure is unknown. This avoids the slightly circular reasoning of assigning species to trophic groups based on network structure and then analysing their roles within the same network. To confirm that our approach is relevant for taxonomic, as well as trophic, groups, we also analysed the roles of species in the five classes with more than 50 species in our dataset (Actinopterygii, Malacostraca, Gastropoda, Polychaeta, and Aves) separately from those of other species.

Identifying key positions

To assess relationships between species' traits and their roles, we first identified the motif positions that explained the most variation in the roles of each trophic and taxonomic group. We performed a principal components analysis (PCA) to collapse the 30-dimensional (intermediate consumers and taxonomic groups) or six-dimensional (basal

resources and top predators) role vectors into orthogonal axes. We then identified the three motif positions that covaried most strongly with the first two axes as “key positions” accounting for a great deal of the variation in species’ roles. These positions are important for distinguishing the roles of different species but may or may not be positions which are important in other contexts (e.g., the most common positions or those which contribute to network stability). We ran separate PCAs for each trophic and taxonomic group as key positions could vary between them.

Association of traits with positions

After identifying the key positions we then used a model-selection approach to determine which traits were most strongly associated with the frequency of each position. We fitted models separately for the frequency of each key position in the roles of each trophic or taxonomic group. To obtain more normal distributions, we log-transformed body masses and scaled and centred body mass and trophic level, the only continuous traits in our dataset. All other traits were treated as categorical variables.

Because of the large number of variables involved, we selected the best-fitting model by building up from a null model containing only an intercept and a random effect of network. The random effect was included to account for differences in species roles both due to environmental factors and due to the different distributions of traits in different food webs. We created a first set of alternative models by adding predictors associated with each trait to the null model in turn. These alternative models took the form:

$$\psi_{ijk} \approx \beta_0 + \beta_1 \text{trait}_{xj} + N_k, \quad (1)$$

where ψ_{ij} is the count of position i for species j in network k , β_0 is a general intercept, β_1 is the effect of the value of trait x (e.g., feeding environment) for species j , and N_k is a random effect of network k . Note that each alternative model included only one trait. Because ψ_{ijk} are frequencies bounded between 0 and 1, all models used a binomial error distribution.

We then ranked these models according to their AIC to determine which trait most improved upon the fit of the null model. We then extended the best-fitting model to create a second set of alternative models by adding the predictors associated with the traits not included in the best-fit model from the first round. We then ranked these models according to their AIC and again selected the best-fitting model as the base for the next set of alternative models. These second set of alternative models took the form

$$\psi_{ijk} \approx \beta_0 + \beta_1 \text{trait}_{xj} + \beta_2 \text{trait}_{yj} + N_k, \quad (2)$$

where all symbols are as described above except that trait x is the trait included in the best-fitting model from the first round and trait y may be any trait except for trait x .

We continued this process until adding an additional trait did not improve on the previous best-fitting model (i.e., no model had $\delta_{AIC} > 2$ relative to the previous best-fitting model). Where there were two or more “best” models with similar AIC scores ($\delta_{AIC} < 2$), we used both models as bases for the next round of models. We fit all models using the function `glmer` (family “binomial”) from the R (R Core Team, 2016) package

lmerTest (Kuznetsova *et al.*, 2014). As trophic level is defined based on network structure, like trophic groups, we repeated our analysis of taxonomic groups omitting all models including trophic level. This did not substantially change our results (see *Supplemental results: within classes* for details).

Results

Trophic groups

We first divided the species into basal resources, intermediate consumers, and top predators and determined the major axes of variation in the roles of each trophic group. The first two axes explained the majority of the variance in species' roles in all cases (58.3% and 33.1%; 33.3% and 20.2%; and 60.2% and 29.8% for the first and second axes of each group, respectively). In each of the trophic groups, positions in the same three motifs were strongly correlated with one or both of the major axes (Figs. 2A, 3A, 4A; Fig. S2, Table S6, *Supplemental results: vector loadings and mean position frequencies*). For basal resources and top predators, these key motif positions denoted the bottom and top positions (respectively) in the apparent competition, three-species chain, and direct competition motifs (positions 2, 4, and 10 for basal resources; positions 1, 3, and 9 for top predators). For intermediate consumers, the key positions were the consumer and resource species in the apparent competition motif (positions 1 and 2) and the consumer species in the direct competition motif (position 9). After identifying these key positions, we could search for associations between traits and the frequency of each key motif.

Basal resources

Many of the traits we considered had little or no variation among basal resources: almost all basal resources had the metabolic category, feeding mode, and feeding type “primary producer”, a trophic level of 1, and mobility level 1 (sessile/floating). Only body mass and feeding environment had enough variation to permit well-fitting models. This restricted the set of possible models and is reflected in the extremely simple best-fit models for this trophic group. The best-fit models for positions 2 and 4 (resources in the apparent competition motif and three-species chain, respectively; Fig 1) included only the network random effect.

The best-fit model for the frequency of position 10 (resource in the direct competition motif; Fig. 1) included feeding environment and as well as the random effect. Pelagic species had significantly lower frequencies of position 10 than did benthic species ($\beta_{Environment: pelagic} = -4.71$, $p = 0.004$; Fig. 2). Benthopelagic species did not have significantly different frequencies of position 10 (Table S3, *Supplemental results: basal resources*). The frequency of position 10 also decreased with increasing body mass ($\beta_{BodyMass} = -30.2$, $p = 0.004$).

Intermediate consumers

The best-fit models for the frequencies of key motifs in the roles of intermediate consumers were more complicated than those for basal resources and all included at least three traits. This is unsurprising given the variety of both species and traits included in this trophic group and the fact that the roles of intermediate consumers nearly fill the space defined by

the frequencies of positions 1, 2, and 9 (Fig. 3A). The best-fit model for the frequency of position 1 (consumer in the apparent competition motif; Fig. 1) was the simplest, including terms for body mass, feeding environment, and feeding type. The frequency of this position increased with the log of body mass ($\beta_{BodyMass}=9.75$, $p<0.001$; Fig. 3B). The frequency of position 1 was significantly lower for benthopelagic species than other species ($\beta_{Environment:benthopelagic}=-1.19$, $p=0.049$), but other feeding environments were not associated with significantly higher or lower frequencies of position 1 (Table S4, *Supplemental results: intermediate consumers*). Feeding type was also included in the best-fit model, but no levels of this term were associated with significantly different frequencies of position 1.

The best-fit model for position 2 (resource in the apparent competition motif; Fig. 1) included terms for all traits except body mass. The frequency of this position decreased with increasing trophic level, but this effect was very small ($\beta_{TrophicLevel}=-0.517$, $p<0.001$; Fig. 3C). Species with the feeding type “herbivore-detritivore”, species with intermediate levels of mobility (i.e, crawlers and facultative swimmers), and species with the feeding modes “grazer” or “predator-scavenger” all had higher frequencies of position 2 ($\beta_{FeedingType:herbivore/detrivore}=3.21$, $p=0.006$; $\beta_{Mobility:crawler}=1.33$, $p<0.001$; $\beta_{Mobility:facultativeswimmer}=1.38$, $p<0.001$; $\beta_{FeedingMode:grazer}=1.14$, $p=0.011$; and $\beta_{FeedingMode:predator/scavenger}=3.28$, $p=0.007$, respectively). Conversely, species feeding in benthopelagic, demersal, or pelagic environments and invertebrates had lower frequencies of position 2 ($\beta_{Environment:benthopelagic}=-0.744$, $p=0.017$; $\beta_{Environment:demersal}=-2.99$, $p<0.001$; $\beta_{Environment:pelagic}=-1.88$, $p<0.001$; $\beta_{MetabolicCategory:invertebrate}=-1.60$, $p<0.001$).

The best-fit model for position 9 (consumer in the direct competition motif; Fig. 1)

included terms for trophic level, feeding mode, environment, and feeding type. Like position 2, the frequency of position 9 decreased with increasing trophic level ($\beta_{TrophicLevel}=-1.37$, $p<0.001$; Fig. 3D). Species with the feeding mode “grazer”, feeding environment “benthopelagic”, and feeding types “herbivore-detritivore” or “omnivore” all had significantly lower frequencies of position 9 ($\beta_{FeedingMode:grazer}=-0.983$, $p=0.020$; $\beta_{Environment:benthopelagic}=-1.84$, $p<0.001$; $\beta_{FeedingType:herbivore/detrivore}=-2.07$, $p=0.005$; and $\beta_{FeedingType:omnivore}=-1.11$, $p=0.004$, respectively). No other levels of any trait were associated with significantly higher or lower frequencies of position 9 (Table S4, *Supplemental results: intermediate consumers*).

Top predators

The best-fit models for key positions in the roles of top predators were much simpler than those for intermediate consumers. Trophic level was included in all three models and appears to be strongly associated with the first PCA axis (Fig. 4A). The frequencies of position 1 (consumer in the apparent competition motif; Fig. 1) and position 3 (top predator in the three-species chain motif) both increased with increasing trophic level, although this relationship was only significant for position 3 ($\beta_{TrophicLevel}=4.44$, $p=0.289$ and $\beta_{TrophicLevel}=1.86$, $p<0.001$ for positions 1 and 3, respectively; Fig. 4B). There was a single species with an unusually high relative frequency of position 1 (the consumer in the apparent competition motif). After removing this potential outlier and repeating our analyses, the best-fit model for position 1 included only the network-level random effect (*Supplemental results: top predators*).

The frequency of position 9 (consumer in the direct competition motif; Fig. 1), in

contrast, decreased with increasing trophic level ($\beta_{TrophicLevel}=-2.09$, $p<0.001$). The best-fit model for the frequency of position 9 also included terms for body mass and metabolic category. The frequency of position 9 decreased as the log of body mass increased ($\beta_{BodyMass}=-11.8$, $p=0.003$; Fig. 4C) and was also lower for invertebrates than for ectotherm vertebrates ($\beta_{MetabolicCategory:invertebrate}=-5.49$, $p=0.013$; Table S5, *Supplemental results: top predators*).

Taxonomic groups

We repeated our analyses for the five most species-rich classes (the only classes with >50 species). One class, Polychaeta, was only represented by intermediate consumers. All other classes included both top predators and intermediate consumers. Metabolic category was constant within each class, all Actinopterygii and all Aves had the same mobility, and all but one Polychaete shared the same feeding environment. These traits were therefore excluded from our models for the relevant classes. The first two PCA axes explained the majority of variation in each case (Fig. 5). While the key positions varied between classes, all positions were in the same three motifs highlighted by our trophic-group analyses: apparent competition, direct competition, and three-species chains (Fig. 5). The traits retained in the best-fit models also varied between classes (Table 1), but feeding environment and trophic level were commonly included (*Supplemental results: within classes*).

Discussion

Analyses within trophic groups

Our results show that for all three trophic groups, key positions were within the same motifs: apparent competition, direct competition, and the three-species chain. For basal resources, the best-fit models relating traits to these positions were very simple. The most complex model, that for position 10, included body mass and feeding environment. Specifically, the frequency of position 10 decreased with increasing body mass and, all else being equal, was higher for pelagic resources than benthic or benthopelagic resources. As pelagic and benthopelagic resources tended to be smaller than benthic resources such as macroalgae, the net result was that benthopelagic resources had the highest frequencies of position 10. Ecologically, this may reflect the higher vulnerability of benthopelagic resources which are within reach of both pelagic and benthic consumers (Fig. S1, *Supplemental results: basal resources*). The dearth of traits retained in our other best-fit models for basal resources suggests that their roles are best predicted using different traits than we considered here –possibly traits related to physical or chemical defences against herbivores (Hay & Fenical, 1988). Such traits, classified as vulnerability traits by Gravel *et al.* (2016), could affect species’ roles if, for example, heavily-defended species tend to be consumed by specialised herbivores with few other prey and hence mainly appear in three-species chains.

Our results for intermediate consumers were more complex: the best-fit models each included several traits. This is not surprising as intermediate consumers were the most numerous and taxonomically diverse trophic group in our dataset. Subdividing this group based on taxonomy or a trait of particular interest might, in future studies, yield clearer

trends. Among the large number of traits included in the best-fit models, we note that feeding environment and feeding type were included in the models for all three key positions. Both of these traits, foraging traits in the framework of Gravel *et al.* (2016), may be particularly useful when modelling trophic interactions. As with basal resources, the feeding environments used by intermediate consumers may affect the numbers and sets of predators and prey that they encounter, thereby shaping their roles.

The possibility that species' feeding environments have strong effects on their roles echoes earlier work using fishes' body masses and foraging depths to predict interactions (Gravel *et al.*, 2013). In both cases, the probability of two species interacting depends upon their encounter probabilities (Bartomeus *et al.*, 2016), with species feeding in similar environments being more likely to encounter each other and hence more likely to interact (Gravel *et al.*, 2013, 2016). For example, a benthic consumer is more likely to encounter, and prey upon, another benthic species than it is to prey upon a pelagic species it will rarely or never encounter. Feeding type (e.g., herbivore) was also included in all models for key positions in the roles of intermediate consumers, suggesting that the type of resources a species consumes likewise shapes its role. Herbivores in particular had unusual roles, perhaps because they interact with basal resources which themselves have unique roles.

Our results for top predators were simpler, with trophic level included in the best-fit models for all three key positions. Trophic level appears to correspond to the first PCA axis for these species and was therefore related to the frequencies of positions 3 and 9, which were strongly correlated with this axis. The inclusion of trophic level in the best-fit model for the frequency of position 1, which was correlated with the second PCA axis,

appears to have been due to the influence of a single outlier and may not reflect a general trend (*Supplemental results: top predators*). Species with higher trophic levels appeared more frequently at the tops of food chains (position 3) and less frequently as direct competitors (position 9). This is possibly because species with higher trophic levels have more of the food web “below” them and therefore more chains available. Species with higher trophic levels may also be more able to exclude competitors than those at lower trophic levels (which appeared in more competition motifs in our dataset). As body size was also included in the best-fit model for position 3 (smaller top predators appeared more frequently in the direct competition motif), both possibilities seem likely. In our dataset, some of these small, low trophic-level top predators are herbivore/detrivores (i.e., *Abatus spp.*) that likely share prey with intermediate consumer herbivore/detrivores as well as other top predators. These herbivore/detrivore predators also consume basal resources as a large proportion of their prey. This creates many chains of length two and eliminates the possibility of motifs like the three-species chain. These exclusions must increase the frequencies of the competition motifs, which require only two trophic levels, and decrease the frequency of the three-species chain motif because of the zero-sum nature of relative motif frequencies.

Taxonomic groups

We also tested for relationships between the traits and roles of species in the five most species-rich classes in our datasets. High-level taxonomic groups (e.g., class or phylum) have previously been shown to predict species’ interactions (Eklöf *et al.*, 2011), suggesting

that we might find clearer relationships between species' traits and roles within a family than across many families. A taxonomic approach also avoids the problems of first using network structure to define trophic groups and then analysing species' roles as defined using that same structure. Notably, all key positions belonged to the same three motifs as those in our analyses by trophic group –apparent competition, direct competition, and the three-species chain– although the set of positions most strongly associated with variation in the roles of each class differed.

Positions within the omnivory motif were not identified as “key positions” in the roles in any class. Despite the fact that the omnivory motif is over-represented in food webs (Stouffer *et al.*, 2007) and may contribute to stability (McCann & Hastings, 1997; Emmerson & Yearsley, 2004), it was not among the most common or most variable positions in our dataset (Table S6, *Supplemental results: vector loadings and mean position frequencies*). Instead, it appears that three-species chains and the two competition motifs contain the most important positions for distinguishing the roles of species within a group (trophic or taxonomic). This reinforces the instincts of researchers who have previously studied some of these motifs (e.g. Hastings & Powell, 1991; McCann *et al.*, 1998; Laws & Joern, 2013) and suggests that they are worthy of further study. In particular, trait-matching within these motifs may differ such that we can predict which motif a given trio of species will form. Feeding environment and trophic level were retained in many best-fit models for classes, suggesting that these traits may be of interest in such studies. The inclusion of feeding environment reinforces our results for trophic groups in suggesting that the use of different environments strongly shapes species' roles. Trophic level, as in our models for top predators, may affect the types of predators and prey a focal species

encounters, again shaping its role. Although trophic level is defined based on network structure in our dataset, there is good agreement between trophic levels derived from network structure and those obtained using stable isotopes (Williams & Martinez, 2004; Carscadden *et al.*, 2012), allowing for trophic level to be a useful trait even when network structure is not known.

Our within-class analyses also included many best-fit models which included only the network-level random effect. As with the basal resources, this likely indicates that traits we did not consider here have large effects on species' roles. Defensive shells, spines, or camouflage, for example, might strongly affect species' interaction partners and hence their roles (Gravel *et al.*, 2016). Where the traits that determine interactions are difficult to predict (Dormann *et al.*, 2017), restricting analyses to within a class may be helpful in future studies. This is because examining species within a single class should reduce some of the "hidden variables" leading to different roles between classes and yield clearer signals for the traits of interest. Moreover, those with expert knowledge about a given class may be able to suggest plausible traits for testing that are likely to affect the roles of species within the focal class but not necessarily species in other classes. Importantly, these benefits do not come at the expense of simplicity. Although resolving fine-scale taxonomic groups can be very difficult, high-level taxa such as classes are straightforward to identify in most cases, facilitating analyses of novel species.

Conclusion

Positions in the same three motifs – three-species chain, apparent competition, and direct competition – were associated with the major axes of variation in the roles of each trophic group and class we considered. This suggests that these motifs will reward further study, particularly with regard to how trait-matching may vary between motifs. Feeding environment consistently emerged as a particularly important trait in structuring patterns of interactions. This is likely because, in order to interact, species first must co-occur in the same environment (Bartomeus *et al.*, 2016). Our results thus support earlier work in emphasising the importance of including co-occurrence in food-web models and suggest that traits influencing co-occurrence are important in structuring species’ roles.

Acknowledgements

This study was supported by a Formas grant (#942-2015-1262) to AE. We would like to thank Ute Jacob for sharing the Lough Hyne and Kongsfjorden datasets, and György Barabás and Jonatan Årevall for providing feedback on the manuscript.

Supporting information

A supporting information file contains the following sections:

Supplemental methods: food web details

Supplemental methods: trait details

Supplemental results: within classes

Supplemental results: basal resources

Supplemental results: intermediate consumers

Supplemental results: top predators

Supplemental results: vector loadings and mean position frequencies

Tables

Table 1: Traits retained in the best-fit models for each trophic group and class analysed. Note that each model also included a random effect of network. Benthic species were the baseline level for feeding environment, deposit-feeders were the baseline level for feeding mode, carnivores were the baseline level for feeding type, ectotherm vertebrates were the baseline level for metabolic category, and level 1: sessile/passive floater was the baseline level for mobility. Body mass and trophic level were treated as continuous traits. For a complete list of levels for each trait, see Table S2.

Group or class	Position	Traits included in best-fit model
Basal resources	2	None
	4	None
	10	Body mass, feeding environment
Intermediate consumers	1	Body mass, feeding environment, feeding type
	2	Feeding environment, feeding mode, feeding type, metabolic category, mobility, trophic level
	9	Feeding environment, feeding mode, feeding type, trophic level
Top predators	1	Trophic level
	3	Trophic level
	9	Body mass, metabolic category, trophic level
Actinopterygii	1	Body mass, feeding environment, trophic level
	2	Trophic level
	9	Feeding environment, feeding type, trophic level
Aves	1	None
	3	Trophic level
	9	Feeding type, trophic level
Gastropoda	2	Feeding environment
	9	Feeding environment, feeding type, trophic level
	10	None
Malacostraca	1	None
	2	Body mass, feeding mode
	9	Feeding environment, feeding mode, trophic level
Polychaeta	2	Trophic level
	9	Trophic level
	10	None

Figure Legends

Figure 1: Set of three-species motifs with positions numbered. Motifs may include one, two, or three unique positions. Within a motif, species (circles) with the same fill occupy the same position.

Figure 2: The roles of basal resources varied with feeding environment. **A)** Here we show the roles of each basal resource plotted against the first two principal components axes. Different feeding environments are indicated by symbol shape and size. Feeding environment was included in the best-fit model for the frequency of position 10 (resource in the direct competition motif; top right). The best-fit models for the other positions included only a random effect of network. We also show the loading of positions 2, 4, and 10 against the same axes. Positions are shown in their motif contexts with the focal positions highlighted in black. **B)** The frequency of position 10 varied with feeding environment and the log of body mass. Here we show the predicted frequency of position 10 for resources in each environment (lines). The frequency of position 10 decreases with increasing body mass and was significantly lower for pelagic resources than benthic or benthopelagic resources. We also show the observed body masses of each basal resource in our dataset (red circles for benthic resources, blue squares for benthopelagic resources, and green diamonds for pelagic resources). Note that because benthic resources were generally much larger than pelagic resources the two groups ultimately had similar frequencies of position 10. Position 10 is highlighted in black in the motif depicted in the upper left.

Figure 3: The roles of intermediate consumers filled the space defined by different proportions of positions 1, 2, and 9. **A)** Here we show the roles of each intermediate consumer plotted against the first two principal components axes. We also show the loading of positions 1, 2, and 9 on these same axes. Positions are shown in their motif contexts with the focal positions highlighted in black. These motif diagrams are repeated in panels B-D. **B)** The frequency of position 1 (the consumer in the apparent competition motif) increased with increasing body mass and varied with feeding environment (indicated by line type). **C)** The frequency of position 2 (a resource in the apparent competition motif) decreased slightly with increasing trophic level but also varied with all other traits except for body mass. For each categorical trait, we show the coefficient ($\pm$ SE) for any levels with significantly higher or lower frequencies of position 2 than the baseline. When identifying these levels, "FT" refers to feeding type, "E" refers to environment, "M" refers to mobility, "MC" refers to metabolic category, and "FM" refers to feeding mode. Baseline levels are given in the caption of Table 1. **D)** The frequency of position 9 decreased with increasing trophic level and varied with feeding environment (indicated by line type), feeding mode, and feeding type.

Figure 4: The best-fit models for all three key positions in the roles of top predators included trophic level. **A)** Here we show the roles of each top predator plotted against the first two principal components axes. Symbol fill indicates trophic level. Note that trophic level displays a clear gradient along the first PCA axis. We also show the loading of positions 1, 3, and 9 on the same axes. Positions are shown in their motif contexts with the focal positions highlighted in black. These motif diagrams are repeated in panels B and C. **B)** The frequency of positions 1 and 3 (consumer in the apparent competition motif and top predator in the three-species chain) increased with increasing trophic level, although this increase was not significant for position 1. Here we show predicted frequencies of position 1 (dotted line) and position 3 (solid line) based on the fixed effects in the best-fit models, over the range of trophic levels observed for top predators in our dataset. **C)** The frequency of position 9 (consumer in the direct competition motif) was related to body mass and metabolic category as well as trophic level. The frequency of this position decreased with increasing trophic level (indicated by line colour) and increasing body mass. For a given body mass and trophic level, invertebrates (solid lines) had lower frequencies of position 9 than other metabolic categories (dotted lines for ectotherm vertebrates, dashed lines for endotherm vertebrates). Here we show the predicted frequencies of position 9 for species in each metabolic category with minimum, mean, and maximum trophic levels, over the range of body masses observed for top predators in our dataset.

Figure 5: The key motif positions most strongly associated with the major axes in variation between species' roles varied by class, but all positions were part of the apparent competition, direct competition, or three-species chain motifs. Here we show the loadings of each motif position on the first two PCA axes of variation in the roles of the five most species-rich classes in our dataset, as well as for species in all other classes. Each PCA was conducted separately.

Species traits, especially feeding environment, shape their roles in marine food webs: Supplemental information

Alyssa R. Cirtwill¹, Anna Eklöf ¹

¹Department of Physics, Chemistry
and Biology (IFM)
Linköping University
Linköping, Sweden

Supplemental methods: food web details

Table S1: Basic information about the food webs used in this study. All webs were used in their original published form except for the Reef web. We removed one species (*Synodus synodus*) from this web prior to calculating species' roles as this fish had no recorded prey and was therefore incorrectly classed as a basal resource.

Web	# Species	# Links	Location	Original source
Kongsfjorden	270	1647	Kongsfjord, Norway	Jacob (unpub.)
Lough Hyne	349	5114	Lough Hyne, Ireland	Jacob (unpub.)
Reef	246	3313	American & British Virgin Islands & Puerto Rico	(Opitz, 1996)
St. Marks	143	1766	St. Marks National Wildlife Refuge, Florida, USA	(Christian & Luczkovich, 1999)
Weddell	488	15880	Weddell Sea, Antarctica	(Jacob <i>et al.</i> , 2011)
Ythan	92	417	Ythan Estuary, Scotland	(Cohen <i>et al.</i> , 2009)

Supplemental methods: trait details

In general, the traits we used are as described in the supplemental information of (Eklöf *et al.*, 2013).

Body mass

Three species in the Kongsfjorden web (*Calanus finnmarchicus*, *Diastylis rathkii*, and *Bylgides groenlandica*) did not have estimated body masses. For these species, we estimated biomasses based on related species present in the same web. *Calanus finnmarchicus* was assumed to have the same body mass as the two other *Calanus* species present in Kongsfjorden and *Diastylis rathkii* was assumed to share the same biomass as the other two *Diastylis* species present. No other *Bylgides* species were present in the Kongsfjorden web. We therefore used the mean biomass of the only two species in our dataset that were in the same family (Polynoidae) to estimate the biomass of *B. groenlandica*.

Trophic level

Each species' trophic level was defined as one plus the average of the trophic levels of its prey (i.e., prey-averaged trophic level).

Environment

The raw data we used in this study described species' feeding environments as one of: "benthic", "pelagic", "benthopelagic", "demersal", "pelagic-oceanic", "reef-associated", "land-based", and "epipelagic/ice-associated". To improve the consistency of environment types across networks, we lumped some levels of feeding environment together. Specifically, we grouped "pelagic-oceanic", and "epipelagic/ice-associated" together with "pelagic" and "reef-associated" with "benthopelagic". Note that the only "epipelagic/ice-associated" species was a single species of krill (*Thysanoessa inermis*) which forages near surface ice. "Pelagic-oceanic" was only used in the reef web, which only labelled two species (phytoplankton and zooplankton) as "pelagic". The feeding environment "reef-associated" was almost entirely found in one network (194 species in the "reef" network, six species in the Lough Hyne network; no "reef-associated" species were found in any other network). To prevent redundancy between this trait and the network-level random effect, we lumped "reef-associated" species together with "benthopelagic" species. "Land-based" species are those such as otters (*Lutra lutra*) and cormorants (*Phalacrocorax aristotelis*) which forage in the water but are obliged to return to land. Such species were present in several webs; we therefore retained "land-based" as a separate feeding environment.

Metabolic category

Metabolic category could take the values of "primary producer", "invertebrate", "ectotherm vertebrate", or "endotherm vertebrate". This trait therefore incorporates some

taxonomic information as well as differentiating between species with different metabolisms.

Mobility

Four categories of mobility were included in this dataset. Mobility level 1 described sessile species and those that passively float (e.g., phytoplankton). Levels 2-4 described species which crawl (level 2), are facultative swimmers (level 3), or are obligate swimmers (level 4). Note that these are very broad categories which do not take into account speed of movement, typical foraging ranges, etc.

Feeding type

Possible values for feeding type in the original data were “carnivorous”, “herbivorous”, “detritivorous”, “herbivorous/ detritivorous”, “omnivorous”, or “none”. The “none” value accounts for primary producers and other basal resources. As “herbivorous” and “detritivorous” species were rare, we labelled them as “herbivorous/detritivorous” to keep the number of possible values for feeding type low.

Feeding mode

Possible values for feeding mode in the raw data were “predator”, “scavenger”, “predator/scavenger”, “grazer”, “suspension feeder”, and “primary producer”. Similar to feeding type, “predator” and “scavenger” species were rare and therefore grouped with the more common “predator/scavenger”.

Table S2: Levels of each trait in our dataset. Baseline levels for each categorical trait are highlighted in bold.

Trait	Levels
log(Body mass)	continuous
Environment	benthic , benthopelagic, demersal, land-based, pelagic
Feeding mode	deposit-feeder , grazer, primary producer, predator/scavenger, suspension-feeder
Feeding type	carnivore , herbivore/detritivore, omnivore, primary producer
Metabolic category	ectotherm vertebrate , endotherm vertebrate, invertebrate
Mobility	1: sessile/passive floater , 2: crawler, 3: facultative swimmer, 4: obligate swimmer
Trophic level	continuous

Supplemental results: within classes

Actinopterygii

The first two PCA axes for the roles of bony fishes explained 41.1% and 20.2% of variation, respectively. As with the intermediate consumers, positions 1, 2, and 9 were most strongly associated with these axes. The best-fit model for position 1 included terms for environment, body mass, and trophic level. The frequency of position 1 increased with increasing body weight ($\beta_{BodyMass}=2.62, p<0.001$) and decreased with increasing trophic level ($\beta_{TrophicLevel}=-0.707, p<0.001$). Benthopelagic fishes had significantly lower frequencies of position 1 than benthic species ($\beta_{Environment:benthopelagic}=-2.07, p=0.044$); demersal and pelagic species did not have significantly different frequencies of position 1 than the baseline for benthic species ($\beta_{Environment:demersal}=1.28, p=0.130$; $\beta_{Environment:pelagic}=-0.233, p=0.859$). When re-running our analyses while excluding any models including trophic level, the best-fit model for the frequency of position 1 included terms for environment and body weight. The frequency of position 1 again increased with increasing body weight ($\beta_{BodyMass}=2.10, p=0.002$) and benthopelagic species again had lower frequencies of position 1 than benthic species, although not significantly ($\beta_{Environment:benthopelagic}=-1.87, p=0.050$). Demersal and pelagic species again had similar frequencies of position 1 to those of benthic species ($\beta_{Environment:demersal}=1.10, p=0.180$; $\beta_{Environment:pelagic}=-0.296, p=0.874$).

The best-fit model for position 2 included the term for trophic level. The frequency of position 2 decreased with increasing trophic level ($\beta_{TrophicLevel}=-0.191, p=0.017$). When we excluded models containing trophic level, the best-fit model for position 2 included the term for log of body mass. The frequency of position 2 decreased with increasing body mass ($\beta_{BodyMass}=-0.877, p=0.012$).

The best-fit model for position 9 included terms for environment, trophic level, and feeding type. As with the other key motifs, the frequency of position 9 decreased with increasing trophic level ($\beta_{TrophicLevel}=-0.522, p=0.005$). Although feeding environment and feeding type were both retained in the best-fit model, no level of either trait was associated with higher or lower frequencies of position 9 than the baseline. When we excluded models containing trophic level, the best-fit model for position 9 included terms for environment. Pelagic species had significantly higher frequencies of position 9 than benthic species ($\beta_{Environment:pelagic}=2.36, p=0.037$); benthopelagic and demersal species had similar frequencies of position 9 to those of benthic species ($\beta_{Environment:benthopelagic}=0.168, p=0.877$ and $\beta_{Environment:demersal}=1.76, p=0.098$, respectively).

Aves

The first two PCA axes for the roles of birds explained 58.0% and 24.1% of variation, respectively. As with top predators, positions 1, 3, and 9 were most strongly associated with these axes. The best-fitting model for position 1 included only the random effect of network. This was also true when we re-ran our analyses excluding any models including trophic level.

The best-fitting model for position 3 included the term for trophic level. The frequency

of position 3 increased with increasing trophic level ($\beta_{TrophicLevel}=0.639$, $p=0.040$). When excluding models containing trophic level, the best-fitting model for position 3 included terms for feeding type. Omnivores had significantly higher frequencies of position 3 than carnivores ($\beta_{FeedingType:omnivore}=1.70$, $p=0.011$) while herbivore/detrivores had similar frequencies of position 3 to those of carnivores ($\beta_{FeedingType:herbivore/detrivore}=-15.0$, $p=0.997$). Note that there were only two birds with the feeding type herbivore/detrivore, and neither ever appeared in position 3.

Finally, the best-fitting model for position 9 included terms for trophic level and feeding type. The frequency of position 9 decreased with increasing trophic level ($\beta_{TrophicLevel}=-1.31$, $p<0.001$). Although feeding type was retained in the best-fit model, no level of this trait was associated with significantly different frequencies of position 9 than that of the baseline. When excluding models containing trophic level, the best-fitting model for position 9 included terms for feeding type. Omnivorous birds had significantly lower frequencies of position 9 than carnivorous birds ($\beta_{FeedingType:omnivorous}=-2.25$, $p=0.035$) while herbivorous/detrivorous birds did not have significantly different frequencies of position 9 ($\beta_{FeedingType:herbivore/detrivore}=-13.0$, $p=0.984$).

Gastropoda

The first two PCA axes for the roles of gastropods explained 51.6% and 16.0% of variation, respectively. Positions 2, 9, and 10 were most strongly associated with these axes. The best-fit model for position 2 included terms for feeding environment, but pelagic species did not have significantly higher or lower frequencies of position 2 than the baseline (benthic species; $\beta_{Environment:pelagic}=-12.8$, $p=0.955$). When re-running our analyses excluding any model including trophic level, the best-fitting model for position 2 again included terms for feeding environment with identical relationships between these terms and the frequency of position 2.

The best-fit model for position 9 included terms for feeding type, environment, and trophic level. The frequency of position 9 increased with increasing trophic level ($\beta_{TrophicLevel}=0.970$, $p=0.016$). No levels of feeding type or environment were associated with significantly higher or lower frequencies of position 9 than the baseline. When excluding models containing trophic level, the best-fitting model included terms for feeding type and environment. No levels of feeding type or environment were associated with significantly higher or lower frequencies of position 9 than the baseline.

The best-fit model for position 10 included only the random effect of network. This was also the case when re-running our analyses excluding models containing trophic level.

Malacostraca

The first two axes for the roles of crustaceans explained 35.5% and 19.8% of variation, respectively. Positions 1, 2, and 9 were most strongly associated with these axes. The best-fitting model for position 1 included only the random effect of network. This was also the case when re-running our analyses and excluding models containing trophic level.

The best-fitting model for position 2 included terms for feeding mode and body mass. The frequency of position 2 again decreased with increasing body mass

($\beta_{BodyMass}=-2.51$, $p<0.001$). Species with the feeding mode "predator/scavenger" had significantly lower frequencies of position 2 than detritivores ($\beta_{FeedingMode:predator/scavenger}=-4.02$, $p=0.003$), while species with feeding modes "grazer" and "suspension-feeder" did not have significantly different frequencies of position 2 ($\beta_{FeedingMode:grazer}=-2.68$, $p=0.060$ and $\beta_{FeedingMode:suspension-feeder}=-10.6$, $p=0.572$, respectively). When re-running our analyses excluding models containing trophic level, the best-fitting model again included terms for feeding mode and body mass, with identical relationships between these terms and the frequency of position 2.

The best-fitting model for position 9 included terms for trophic level, feeding mode, and environment. The frequency of position 9 decreased with increasing trophic level ($\beta_{TrophicLevel}=-1.51$, $p<0.001$). Species with the feeding modes "predator/scavenger" and "suspension-feeder" had significantly higher frequencies of position 9 than the baseline (detritivores; $\beta_{FeedingMode:predator/scavenger}=3.11$, $p=0.012$ and $\beta_{FeedingMode:suspension-feeder}=3.97$, $p=0.025$, respectively). Grazers did not have significantly different frequencies of position 9 ($\beta_{FeedingMode:grazer}=1.93$, $p=0.092$). Benthopelagic and pelagic species had significantly lower frequencies of position 9 than benthic species ($\beta_{Environment:benthopelagic}=-3.61$, $p=0.002$ and $\beta_{Environment:pelagic}=-1.75$, $p=0.049$, respectively). When re-running our analyses excluding models containing trophic level, the best-fitting model included terms for feeding mode and environment. Species with the feeding mode "suspension-feeder" had significantly higher frequencies of position 9 than the baseline (detritivores; $\beta_{FeedingMode:suspension-feeder}=4.10$, $p=0.022$) while grazers and predator-scavengers did not have significantly different frequencies of position 9 ($\beta_{FeedingMode:grazer}=1.81$, $p=0.108$ and $\beta_{FeedingMode:predator-scavenger}=1.10$, $p=0.292$, respectively). Benthopelagic species had significantly lower frequencies of position 9 than benthic species ($\beta_{Environment:benthopelagic}=-3.27$, $p=0.005$) while pelagic species did not have significantly different frequencies of position 9 ($\beta_{Environment:pelagic}=-1.14$, $p=0.095$).

Polychaeta

The first two axes for the roles of polychaetes explained 33.7% and 26.2% of variation, respectively. Positions 2 and 9 were strongly associated with the first two axes and position 10 was more weakly associated with the first axis. Position 1 was weakly associated with the second axis, to a similar extent as that of position 10 and axis 1. The best-fitting models for position 1 and position 10 included only the random effect of network. This was also the case when repeating our analyses excluding any models including trophic level.

The best-fitting models for position 2 and position 9 included trophic level. The frequency of position 2 decreased with increasing trophic level, as did the frequency of position 9 ($\beta_{TrophicLevel}=-0.732$, $p=0.001$ and $\beta_{TrophicLevel}=-0.938$, $p=0.033$, respectively). When repeating our analyses excluding models containing trophic level, the best-fitting model for position 2 included only the network effect and the best-fitting model for position 9 included terms for feeding type. Herbivore/detritivores and omnivores did not have significantly different frequencies of position 9 than carnivores ($\beta_{FeedingType:herbivore/detritivore}=-0.442$, $p=0.785$ and $\beta_{FeedingType:omnivore}=-2.33$, $p=0.177$, respectively).

Supplemental results: basal resources

Table S3: Parameter estimates and p -values for the best-fitting models of the frequencies of positions 2, 4, and 10 in the roles of basal resources. ‘NA’ indicates that a particular effect was not included in the best-fitting version of a model. The best-fit models for positions 2 and 4 included only the intercept and a random effect of network (not shown). The best-fit model for position 10 included body mass, feeding environment, and the random effect. Benthic species were the baseline (intercept) feeding environment. Note that feeding mode, feeding type, metabolic category, trophic level, and mobility were nearly invariant for the trophic levels in this dataset and could not be included in our models. Coefficients relate to the logit of the frequency of each position.

Term	Position 2		Position 4		Position 10	
	β	p	β	p	β	p
Intercept	1.56	<0.001	-3.93	<0.001	-1.07	0.256
$\log(BodyMass)$	NA		NA		-30.2	0.004
$Environment_{Benthopelagic}$	NA		NA		1.50	0.362
$Environment_{Pelagic}$	NA		NA		-4.71	0.004

High frequencies of position 10 (the prey position in the apparent competition motif) may reflect higher vulnerability as this motif requires two predators to share a single prey. Indeed, in our dataset the frequency of position 10 was positively and moderately strongly correlated with the vulnerability of basal resources ($R^2=0.46$; Fig. S1). This correlation is less than one both because we use normalised frequencies (i.e., proportions of species’ roles made up by each position) rather than raw counts and because a given consumer-resource combination may form part of a three-species chain, omnivory motif, or other configuration than the direct competition motif.

Figure S1: The frequency of position 10 in the roles of basal resources increased with vulnerability.

Supplemental results: intermediate consumers

Table S4: Parameter estimates and p -values for the best-fitting model of the frequencies of positions 1, 2, and 9 in the roles of intermediate consumers. The best-fitting model for the frequency of position 1 included terms for body mass, feeding environment, and feeding type, in that order. The best-fitting model for the frequency of position 2 included terms for all traits except body mass. The best-fitting model for the frequency of position 9 included trophic level, feeding mode, feeding environment, and feeding type. Baseline levels for each trait are given in the caption of Table S2.

Term	Position 1		Position 2		Position 9	
	β	p	β	p	β	p

Supplemental results: top predators

Table S5: Parameter estimates and p -values for the best-fitting models of the frequencies of positions 1, 3, and 9 in the roles of top predators. ‘NA’ indicates that a particular effect was not included in the best-fitting version of a model. The best-fitting models for the frequencies of position 1 and 3 included trophic level, while the best-fitting model for the frequency of position 9 included trophic level, body weight, and metabolic category. Ectotherm vertebrate was the baseline level of metabolic category. Coefficients refer to effects on the logit of the frequency of each motif.

Term	Position 1		Position 3		Position 9	
	β	p	β	p	β	p
Intercept	-11.1	0.161	-2.12	<0.001	2.45	0.116
log(Body Mass)	NA		NA		-11.8	0.003
<i>MetabolicCategory</i> _{ectothermvertebrate}	NA		NA		-1.76	0.255
<i>MetabolicCategory</i> _{invertebrate}	NA		NA		-5.49	0.013
Trophic Level	4.39	0.289	1.86	<0.001	-2.10	<0.001

The relationship between trophic level and the frequency of position 1 was weak and appeared to be strongly influenced by a potential outlier. This species, *Galeocerdo cuvier* – the tiger shark, was by far the most generalist top predator in our dataset and apparent competition (position 1) accounted for 81.5% of its role. With 167 different prey, it is not surprising that *G. cuvier* would consume many prey that do not directly interact and thereby create many apparent competition motifs. Indeed, the frequency of position 1 in a species’ role was very strongly and positively correlated with its number of prey ($R^2=0.89$). In contrast, generality was weakly and negatively correlated with the frequencies of positions 3 and 9 ($R^2=-0.12$ and $R^2=-0.37$, respectively). As *G. cuvier* is a potential outlier with respect to generality, trophic level, and the frequency of position 1, we re-fit the best-fit model for position 1 excluding *G. cuvier*. In this case trophic level was not significantly related to the frequency of position 1, leading us to conclude that *G. cuvier* is indeed an outlier and was the primary driver of this model. As no other traits were included in the best-fit model, it appears that the frequency of position 1 is not strongly affected by the traits we considered here.

Supplemental results: vector loadings and mean position frequencies

Table S6: Correlations between motif positions and the two PCA axes explaining most variation in the roles of basal resources, intermediate consumers, and top predators. Position numbers correspond to those in Fig. 1 (*Main Text*). Note that positions 1 and 2 make up the apparent competition motif, positions 3, 4, and 5 form the three-species chain motif, and positions 9 and 10 comprise the direct competition motif. ‘X’ indicates that a position could not be occupied by a trophic group (e.g., basal resources cannot occupy consumer positions).

Figure S2: Positions most strongly associated with the two major axes of variation in the roles of basal resources, intermediate consumers, and top predators. We show the proportion of variation in species' roles captured by each axes in parentheses. Position numbers are as in Fig. 1 (*main text*). We also show each position in its motif context, with the numbered position highlighted in black.

Table S7: Mean and standard deviation of each position, for each trophic group. Positions where impossible for a trophic group are indicated by ‘X’.
