ABSTRACT

Background Hip and groin injuries are common in men’s professional football, but the time-trend of these injuries is not known.

Aim To investigate hip and groin injury rates, especially time-trends, in men’s professional football over 15 consecutive seasons.

Study design Prospective cohort study.

Setting Men’s professional football.

Methods 47 European teams were followed prospectively for a varying number of seasons between 2001/02 and 2015/16, totalling 268 team-seasons. Time-loss injuries and individual player exposure during training and matches were recorded. Injury rate was defined as the number of injuries/1000 h and injury burden as the number of lay-off days/1000 h. Time-trends for total hip and groin injuries and adductor-related injury rates were analysed using Poisson regression, and injury burden was analysed using a negative binomial regression model.

Results Hip and groin injuries contributed 1812 out of 12 736 injuries (14%); with adductor-related injury as the most common of hip and groin injuries (n=1139, 63%). The rates of hip and groin injury and adductor-related injury were 1.0/1000 h and 0.6/1000 h, and these rates decreased significantly with on average 2% (Exp(b)=0.98, 95% CI 0.97 to 0.99, p=0.003) and 3% (Exp(b)=0.97, 95% CI 0.95 to 0.99, p<0.001) per season (year on year), respectively. The seasonal trend of hip and groin injury burden did not improve (Exp(b)=0.99, 95% CI 0.97 to 1.01, p=0.40).

Conclusions Hip and groin injuries constitute a considerable part of all time-loss injuries in men’s professional football. Although there was a promising slight decreasing trend in the rates
of hip and groin injury (as a category) and adductor-related injury (as a specific diagnosis), the injury burden remained at a consistent level over the study period.
INTRODUCTION

Professional football has high injury rates, with an average a player sustaining two time-loss injuries per season.1 Hip and groin injuries (HGI) are among the most common football injuries and account for 12-16% of all recorded time-loss injuries per season in men’s professional football.2 Similarly, a recent study of male football players in Qatar found that HGI accounted for 18% of all time-loss injuries.3 This high rate is probably due to the repetitive involvement of sprinting, kicking and change of direction.4-6

In a systematic review on different football codes a stable trend for total HGI rate was found with an increasing trend of intra-articular hip joint conditions over the past decade.7 This trend could reflect an actual increase of hip injuries or reflect diagnostic changes, considering the increasing rate of arthroscopic hip surgery seen both in the USA and Europe over the last 10-15 years.8-9 There is thus a need for studies on HGI in sports with longer follow-up periods and using appropriate time-trend analyses.10

The aim of this study was to investigate HGI rates, especially time-trends, in men’s professional football over 15 consecutive seasons. Our hypothesis was that the overall HGI rate would be stable over multiple seasons.
MATERIALS AND METHODS

This is a sub-study of the Union of European Football Associations (UEFA) Elite Club Injury Study,\(^1\) including some seasonal data on HGI published previously.\(^5\) In total, 47 men’s professional teams from 16 European countries were followed over a varying number of seasons (on average 5.7 seasons per team, range 1 to 15) from 2001/02 to 2015/16. The study has involved 3055 individual players (7756 player-seasons) and 268 team-seasons. Nine teams participated the inaugural year of the study, but the study has expanded and in the 2015/16 season 28 clubs were included. The study design adhered to the consensus statement on injury definitions and data collection procedures in football,\(^11\) and the overall methodology has been reported in detail elsewhere.\(^12\) The recent Doha agreement on terminology of groin pain,\(^13\) a clinically-based taxonomy to improve standards in research of HGI, was used to classify all the HGIs. During this procedure, all HGIs were re-classified by the primary author from the Orchard Sports Injury Classification System (OSICS) used in the database.\(^14\) For the purpose of this sub-study, injuries were categorized according to the Doha agreement on terminology of groin pain into adductor-related, iliopsoas-related, pubic-related, inguinal-related, hip joint-related and other causes of groin pain.\(^13\) Compared with the classification used in our previous study, rectus abdominis tendinopathy and symphysitis/pelvic stress fracture were grouped into the pubic-related category. Consequently, the category “Other causes of groin pain” includes diagnoses such as groin enthesiopathy and groin tendinopathy as well as nerve entrapment.
**Inclusion criteria and definitions**

All players in the first team squads each season were invited to participate. Players who were transferred or finished their contracts due to other reasons before the end of a season were included for as long as they participated in first team activities. Injury was defined according to time-loss, and players were considered injured until the club medical staff allowed full participation in training and availability for match selection.\textsuperscript{11-12} In this study a recordable HGI was defined as an acute or overuse injury located to the hip (the hip joint and surrounding soft tissues) or groin (the junction between the anteromedial part of the thigh and the lower abdomen) regions.\textsuperscript{5 11} All operational definitions used in this sub-study are seen in table 1. Re-injuries were defined according to the concept of early recurrences.\textsuperscript{11}

\left( \frac{\Sigma \text{lay-off days}}{\Sigma \text{exposure hours}} \right) \times 1000
\]

---

**Data collection**

Baseline player data collection and consent was collected once yearly at the time of inclusion. A member of each club’s medical team or technical staff registered individual exposure in minutes during club and national team training sessions and matches. A club medical officer (physician or physiotherapist) recorded all injuries immediately after the incident. Injury cards and attendance records were sent to the study group monthly, starting with July each season during the pre-season preparation period and ending in May the following year. If a player was injured at the end of the season, the study controllers collected additional information on when the player was considered fully fit to return to play in the off-season. Prompt feedback was given to the participating teams by our study controllers in order to correct missing or unclear data. Seasonal data were aggregated on a team level.

**Statistical analyses**

Injury rate (IR) was calculated as the number of injuries per 1000 h with corresponding 95% CI. Injury burden was calculated as the number of lay-off days per 1000 h with corresponding 95% CI. Lay-off days was presented as mean ± SD. Poisson regression was used to analyse seasonal trend in total HGI, and sub-groups adductor-related injury, acute and overuse injury, with
number of injuries as dependent variable, season as independent variable and exposure entered as an offset in the model. A negative binomial regression model was used for injury burden, due to better model fit.\textsuperscript{15} All models were adjusted for overdispersion according to Pearson. A 2-year moving average (MA) approach, by summarising two consecutive seasons and averaging their values, was also used in order to smooth out large seasonal variations and presented as seasonal average percent change.\textsuperscript{16} As a sensitivity analysis, the aggregated IR for the 610 HGIs in the 2001/02 to 2007/08 seasons, as reported previously,\textsuperscript{5} was also compared with the aggregated IR for the subsequent eight seasons 2008/09 to 2015/16 seasons. A rate ratio (RR) with 95% CI was used for IR comparisons between the two seasonal blocks (2001/02 to 2007/08 and 2008/09 to 2015/16) and between match and training. The significance level was set at p<0.05.
RESULTS

In total, 12 736 injuries were registered during 1 816 071 exposure hours (1 529 387 training and 286 684 match). HGI was diagnosed in 1812 cases (912 training and 900 match), constituting 14% of all injuries (table 2). The overall HGI rate was 1.0/1000 h, the match injury rate being five times higher compared with training (IR 3.1 vs. 0.6/1000 h; RR 5.3, 95% CI 4.8 to 5.8). In effect, a men’s professional football club with approximately 25 players in the squad would suffer from about six HGI per season when averaging the whole study period. The HGI rate reduction was 12% in the 2008/09 to 2015/16 seasons compared with the 2001/02 to 2007/08 seasons (IR 0.96 vs. 1.08/1000 h; RR 0.88, CI 95% 0.80 to 0.97); see online supplementary appendix 1 for detailed data covering the 2001/02 to 2007/08 seasons. Acute cause for HGI was seen in 888 cases (49%) and overuse in 910 cases (51%), respectively (missing data in 14 cases).
Table 2 Hip and groin injury frequency and rate between 2008/09 and 2015/16 in European professional football.

†† Percentage of players with hip and groin injury out of the total number of players participating.
§ Injury rate expressed as injuries/1000 hours exposure.
**Time-trends and injury characteristics**

The seasonal trend for HGI rates was statistically significant, with an average annual decrease of 2% per season ($\text{Exp(b)}=0.98$, 95% CI 0.97 to 0.99, $p=0.003$, figure 1), and where the 2-year MA approach indicated an average annual IR decrease of 1.8%. This was mainly due to a decrease in the match IR, with an average annual decrease of 2.7% ($\text{Exp(b)}=0.97$, 95% CI 0.96 to 0.99, $p=0.003$, MA 2.4% decrease per season, figure 2), whereas the training IR was stable over the study period ($\text{Exp(b)}=0.99$, 95% CI 0.97 to 1.01, $p=0.50$, MA 0.01% decrease per season, figure 3).

In effect, a men’s professional football club, with a typical 25-player squad, which suffered from seven HGIs per season on average in 2001/02 could expect a decrease to fewer than six HGIs per season at the end of the study period. The seasonal trend of HGI burden as described by lay-off days did not change significantly ($\text{Exp(b)}=0.99$, 95% CI 0.97 to 1.01, $p=0.40$, figure 4), although the 2-year MA approach indicated an average annual decrease of 1.9%. Consequently, injury severity as measured by lay-off days slightly increased, not paralleling the decrease in HGI rate. Regarding injury onset, a statistically significant 3% decrease per season was seen for acute HGIs ($\text{Exp(b)}=0.97$, 95% CI 0.96 to 0.99, $p<0.001$, MA 2.3% decrease per season), while overuse HGI injury rates were stable with no statistically significant trend ($\text{Exp(b)}=0.99$, 95% CI 0.98 to 1.01, $p=0.43$, MA 1.8% increase per season); see online supplementary appendix 2 and 3.

*Figures 1-4 near here*
The most common HGI was adductor-related injury, totalling 1139 cases (63% of all HGIs), thus making adductor-related injury twice as common as all other HGIs. The adductor-related IR was 0.6/1000 h (table 3), the match injury rate being 6 times higher compared with training (IR 2.2 vs. 0.3/1000 h; RR 6.3, 95% CI 5.7 to 7.1). Adductor-related injury also showed a statistically significant seasonal trend with an average annual decrease of 3% (Exp(b)=0.97, 95% CI 0.95 to 0.99, p<0.001, figure 5), and where the 2-year MA approach indicated an average annual IR decrease of 2.7%. Adductor-related injury had the highest injury burden of all HGIs (table 3).

Figure 5 near here

The second most common HGI was iliopsoas-related injury (8% of all HGIs), whereas pubic-related, inguinal-related and hip-related injuries each constituted approximately 3-4% of all HGIs (table 3). Hip-related injury was noted in 73 cases and the highest seasonal frequency (n=13) was registered already in the inaugural 2001/02 season; hereafter the number of cases registered each season was lower and rather stable in spite of an increasing number of participating teams and players in the study over the years. The most common diagnosis in this clinical entity was hip joint synovitis (n=36), constituting the main diagnosis for half of all hip-related injuries, and another 11 cases were classified as hip cartilage lesions. Femoroacetabular impingement (FAI) was registered as the main diagnosis in only 10 cases (2 during the 2001/02 to 2007/08 seasons and 8 during the 2008/09 to 2015/16 seasons, respectively). Seasonal time-trend analyses were not computed for the iliopsoas-related, hip-related, pubic-related and inguinal-related injury groups due to the limited number of injuries.
Re-injuries and multiple HGIs in the same season

In total, 11% of all HGIs were re-injuries; 11% in the adductor-related injury group, whereas in the pubic-related and hip-related injury groups more than one out of four injuries were re-injuries (table 3). Of the 1401 players who sustained an HGI, 1078 (77%) had only one injury during the season, 253 (18%) had two injuries, and 70 (5%) suffered three or more injuries in the same season. On an individual level, 24% (208/879) and 20% (25/126) of players sustaining an adductor-related and iliopsoas-related injury, respectively, will incur one or more additional HGI in the same season.

DISCUSSION

The principal finding of this study was that HGIs among male professional football players appear to have a slight decreasing trend over the 15-year observation period. This trend was mainly due to a decrease in adductor-related injuries, and these are positive findings even though the clinical importance in the short-term is limited. However, there was no decreasing trend seen for injury burden, suggesting that the slight reduction in number of HGIs was countered by a slight increase in severity of injury as measured by days lost to training and matches.

Hip and groin injury epidemiology

In a systematic review of prospective studies on groin injuries in senior football, every eighth time-loss injury affected the groin.10 In the current study, HGIs made up 11-17% of all injuries, thus extending the knowledge of the existing literature.5 17-19 A certain amount of additional unrecorded complaints could be expected, since previous studies have shown that the prevalence of hip and groin pain during a season can be up to 70%.20-22 This is probably due to the fact that the pain often is insidious in onset and footballers play through a certain degree of discomfort. The use of a time-loss injury definition, as in the current study, therefore underestimates the overall HGI problem in football. On the other hand, time loss injuries capture injuries with a clear impact for the teams since players are unavailable to train and play matches.

In the current study, we report an even distribution of acute and overuse injuries, even though there was a slight decreasing trend of acute injuries, which is in contrast to previous studies on both sub-elite male football as well as professional football in Qatar reporting about 40% of the HGIs to be of acute onset.3,6
In the present study, seasonal time-trend analyses showed a significant decrease of HGI of approximately 2% per season which is in contrast to previous studies on different football codes. In our previous study, the HGI rate was stable over seven consecutive seasons as assessed by visual inspection without any formal time-trend analysis being carried out at that time. In the current study involving another eight seasons a 12% rate reduction was identified between the first and second study periods (2001/02 to 2007/08 and 2008/09 to 2015/16). A change of trend was noted mainly from the 2011/12 season and onwards where the main contributing factor was a decrease of the HGI rate during match play.

Increased caution by the players and medical staffs upon deciding whether a player with minor hip and groin symptoms is eligible for match play, and a wider use and implementation of preventive training might contribute to this. However, injury burden as described by lay-off days did not show a significant decreasing trend, indicating that even though the HGI rate is decreasing, the number of lay-off days for these injuries remains high. From a team perspective, this is an important finding, since injury burden better describes the effects of an injury type for a club than injury rate alone. Even though injury burden may also underestimate the consequences of injuries not leading to time-loss, further analysis of this aspect of injury epidemiology is warranted.23-24

**Injury characteristics**

Adductor-related injury was the most frequently reported entity, making up just about two-thirds of all HGIs. This study thereby adds further evidence that adductor-related injury is the most
common HGI in football.\textsuperscript{2-3, 6} Interestingly, we found a significant decrease in the rate of adductor-related injury, and this has to our knowledge not been shown in football or any other sport previously. It has been suggested that eccentric forces stressing the musculotendinous complex when kicking and changing directions contributes to adductor-related injury.\textsuperscript{22} Moreover, relative weakness of hip adduction is a risk factor for groin injury.\textsuperscript{25}

In previous studies on treatment of long-standing adductor-related groin pain, an active strengthening programme showed effect both in the short-term (odds ratio of 12.7 in favour of the active treatment group upon return to sports without groin pain) and in the long-term (significantly better treatment outcomes in the subgroup of football players).\textsuperscript{26-27} Accordingly, groin injury preventive measures have focused on active strength and coordination exercises, with emphasis on the adductor and abdominal muscles.\textsuperscript{25} We hope that the use of these prevention strategies and an increased overall knowledge on HGI in the medical staffs of professional football clubs accounts for the decreasing trend of these injuries.

Interestingly, the second most common entity of HGI constitutes other causes of groin pain. This highlights the diagnostic challenges of HGI and points toward the historical problem with different taxonomy on HGI without consensus.\textsuperscript{13} On a positive note, this entity had the shortest lay-off time and lowest re-injury rate of all HGI indicating somewhat less severe injuries in this unspecified group of injuries.

\textbf{Recurrent injury - a clinical concern}
Previous HGI has been identified as the most prominent risk factor for HGI and in this respect re-injuries are known to cause longer lay-off times.4-5,28-29 For example, Árnason et al. reported a sevenfold increased risk of groin injury in footballers with previous groin injury.30 In our previous study, re-injuries accounted for 15% of all HGIs.5 In the current study, however, the average re-injury frequency was 11% when analysing the whole study period, indicating a slight decrease over the study period even though this was not specifically analysed. It could be speculated that one cause for this could be that more cautious and specific rehabilitation programmes (e.g. focusing on movement patterns, abdominal and adductor strength and complete physical conditioning) have been implemented for adductor-related and iliopsoas-related injuries where the re-injury frequencies were lower than for other entities.27 However, the scientific evidence for treatment strategies of groin pain is generally low, with moderate evidence for active exercise therapy or multimodal treatment in long-standing adductor-related groin pain.31 Another plausible explanation could be that more attention is paid to individual load, mainly the acute to chronic workload ratio, since this has been shown to be an important predictor of injury.32 However, we also found that 23% of players with a HGI would suffer from at least one more HGI during the same season. Caution concerning symptoms of HGI is therefore recommended throughout the whole season for players who have had a time-loss HGI and continuous secondary preventive measures should be considered.

**Hip-related injuries**

The increase in hip-related injuries reported in other football codes during recent years,7 could not be reproduced in our study in spite of not being able to carry out the formal time-trend analyses due to few cases per season which is a limitation of the method. The physical nature
including full speed tackling, forceful blocks as well as high energy falls in e.g. Australian Rules football and American football could explain the difference between football and these sports. The most common hip-related diagnosis in our study was hip joint synovitis, which merely may reflect just temporary overload and tend to resolve rather quickly. This notion is supported by the fact that most of the hip synovitis injuries were classified as mild or moderate and the mean lay-off was clearly lower than the mean lay-off for the whole HGI group (6 vs. 16 days).

We found only 10 cases with FAI as the main diagnosis on the injury card which is less than one percent of all HGI. It is, however, still possible that FAI was a contributing factor in some of the other hip-related injuries such as joint synovitis or joint cartilage lesion. Nevertheless, considering that previous studies have indicated that radiographic cam-lesions are more prevalent in footballers, our study does not support the idea that FAI is an increasing cause for injury in professional football. Cam and pincer changes are to be considered as morphological variants of the femur and acetabulum, but this does not automatically imply pathology in the form of the FAI syndrome. Radiological signs of FAI is also frequently observed in patients with e.g. longstanding adductor-related pain, and there is a weak correlation between hip morphology and symptoms.

**Strengths and limitations**

The principal strength of the current study is the prospective design over 15 consecutive seasons with a comprehensive dataset on a homogenous group of male professional footballers and terminology adherent to the recent Doha agreement on terminology of groin pain. To the best
of our knowledge, this is one of the largest cohorts ever to be studied prospectively for HGI in professional sports.36-38

We note four additional limitations. First, there were no defined specific diagnostic criteria for different HGI to guide the medical staff. The diagnoses were solely based on the best clinical practice in each club and from our previous study we know that 40% relied on clinical examination exclusively without additional imaging.5 It is also well-known that the number of differential diagnoses are considerable concerning HGI and the lack of common terminology for groin pain and injuries before the Doha consensus may have influenced the number of unspecific diagnosis. This could partly explain why such a substantial number of cases were diagnosed as “groin enthesiopathy” and “groin tendinopathy”. Some of these injuries could probably have been classified in the adductor-related or iliopsoas-related injury groups, had these entities been chosen directly by the club medical staffs. This reflects a problem with reclassifying to the somewhat broader Doha agreement on terminology entities retrospectively.

A second limitation is that HGIs often present with both primary and secondary, and even tertiary, symptoms, which is known to increase lay-off times.4 This study is, however, unable to identify players with two or more diagnostic entities of HGI occurring simultaneously, since only the main diagnosis is entered and systematically OSICS coded in the database. Third, no information on specific treatment details, nor preventive strategies, was collected, and it would have been interesting to relate different treatment plans to lay-off times and recurrence rates as well as the effect of preventive measures on HGI rate. Finally, the interpretation of additional HGI during the same season should be made bearing in mind that an injury sustained in the fall
will have a higher re-occurring risk during the season than an injury sustained in the spring. If, on the other hand, an approach using a calendar year would be used, some players would be “exposed” to the period in between seasons, where rest and rehabilitation is part of normal life for a professional football player.
WHAT ARE THE NEW FINDINGS?

- Hip and groin injury rates have decreased slightly over the past 15 years in men’s professional football, including adductor-related injuries which is the most common clinical entity.

- HGI burden remained unchanged – this metric takes both the rate and severity of injuries into consideration.

- Despite the recent surge in the number of hip arthroscopies being carried out worldwide, hip-related injuries continue to have a low time-loss injury rate in men’s professional football.

HOW MIGHT IT IMPACT ON CLINICAL PRACTICE?

The slight decreasing trend in the rate of HGI, as shown in the current study, is a promising finding and should motivate players, medical staffs and coaches to incorporate recent evidence when working with HGI treatment and prevention.
Acknowledgements

The authors would like to thank the participating clubs (coaching and technical staff, medical teams and players) for their participation in the study. Henrik Magnusson, MSc, is also acknowledged for statistical advice.

The Football Research Group has been established in Linköping, Sweden, in collaboration with Linköping University and through grants from the Union of European Football Associations, and the Swedish National Centre for Research in Sports.

Contributors

JW and MW were responsible for the conception and design of the study. JW and the statistical advisor conducted the analyses which were planned and checked with MW, MH and JE. All authors contributed to the interpretation of findings and had full access to all data. JW wrote the first draft of the paper which was critically revised by MW, MH and JE. The final manuscript has been approved by all authors. MW is the study guarantor.

Funding

This study was funded by grants from the Union of European Football Associations (UEFA) and Swedish National Centre for Research in Sports.

Ethics approval

The study design was approved by the UEFA Medical Committee and the UEFA Football Development Division.
Provenance and peer review

Not commissioned; externally reviewed.

§ Injury rate expressed as injuries/1000 hours exposure

Due to a database update after the 07/08 season, the number of HGIs were adjusted to 610 from the original 628 analysed in our previous study. This was due to reclassification of 18 HGIs to mainly thigh and pelvic diagnoses.
