Abstract
Nonlinear grey-box identification of industrial robots is considered. A three-step identification procedure is proposed in which parameters for rigid body dynamics, friction, and flexibilities can be identified only using measurements on the motor. In the first two steps, good initial parameter estimates are derived which are used in the last step, where the parameters of a nonlinear physically parameterized model are identified directly in the time domain. The procedure is exemplified using real data from an experimental industrial robot.

1. INTRODUCTION

System identification in robotics is a vast research area and can be divided into, at least, three different levels or application areas. These levels involve the estimation of the kinematic description, the dynamical model (often divided into rigid body and flexible body dynamics), and the joint model (e.g., motor inertia, gear box elasticity and damping, motor characteristics, and friction parameters). Some results on the latter two areas are mentioned in Section 4. An overview of identification in robotics can also be found in (Kozlowski, 1998).

In the work presented here, a three-step identification procedure is proposed in which parameters for rigid body dynamics, friction, and flexibilities can be identified only using measurements on the motor side of the flexibility. The main point is the last step, where the parameters of a nonlinear physically parameterized model (a nonlinear grey-box model) are identified directly in the time domain. The first two steps give special attention to the problem of finding good initial parameter estimates for the iterative optimization routine. The procedure is exemplified using real data from an experimental industrial robot.

The work reported here is closely related to the problems considered in, e.g., (Östring et al., 2003; Isaksson et al., 2003). In (Östring et al., 2003), a method is applied where inertial parameters as well as parameters describing the flexibility can be identified directly in the time domain. This is done by utilizing a user-defined model structure in the System Identification Toolbox (SITB). However, only linear models were considered in their work. (Isaksson et al., 2003) consider grey-box identification of a two-mass model with backlash, where black-box modeling is used to find initial parameter values.

The paper is organized as follows. In Section 2 the nonlinear grey-box identification problem is briefly described and Section 3 shows the nonlinear robot model used for identification. The three-step identification procedure is presented in Section 4. In Section 5 the data collection is described, and Section 6 shows the results from applying the proposed identification procedure to
the experimental data. Finally, Section 7 contains some conclusions and notes on future work.

2. NONLINEAR GREY-BOX IDENTIFICATION

The starting point for the nonlinear grey-box identification is the continuous time state space model structure

\[ \dot{x}(t) = f(t, x(t), \theta, u(t)) \quad (1a) \]
\[ y(t) = h(t, x(t), \theta, u(t)) + e(t) \quad (1b) \]

where \( f \) and \( h \) are nonlinear functions. \( x(t) \) is the state vector, \( u(t) \) and \( y(t) \) are input and output signals, \( e(t) \) a white measurement disturbance signal, and \( t \) denotes time. Finally \( \theta \) is the vector of unknown parameters. Given a set of input/output-data the aim is to determine the parameter vector that minimizes the criterion

\[ V_N(\theta) = \frac{1}{N} \sum_{i=1}^{N} e^2(t, \theta) \quad (2) \]

where \( e(t) \) denotes the prediction error

\[ e(t, \theta) = y(t) - \hat{y}(t, \theta) \quad (3) \]

The experiments presented in this paper will utilize the nonlinear grey-box model structure NLGREY, available in a beta version of a nonlinear extension to the System Identification Toolbox (SITB), (Ljung, 2003). The model structure NLGREY is similar to the idgrey model structure in SITB. The model can be either a discrete or continuous time state space model, and it is defined in a Matlab m-file/mex-file. In the current version of the software, only OE-models can be used, i.e., only additive white noise, \( e(t) \), on the output. The prediction \( \hat{y}(t; \theta) \) then becomes the simulated output of the model (1) with the input \( u(t) \) (without \( e(t) \)) for the current parameter vector \( \theta \). The data set, \( \{y, u\} \), is put into an iddata object and \( \theta \) is estimated by applying a prediction error method, which performs a numerical optimization of the criterion (2) by an iterative numerical search algorithm. This search algorithm involves simulation of the system for different values of \( \theta \). The user specifies an initial parameter vector and it is also possible to fix some components in \( \theta \). To speed up the numerical optimization, the simulation model is implemented in a mex-file (C-code).

3. ROBOT MODEL

The industrial robot arm that will be studied in this paper is, for movements around an axis not affected by gravity, modeled by a two-mass flexible model which is illustrated in Figure 1. A two-mass model is probably too simple to describe the true system, see, e.g., (Ostring et al., 2003) or Figure 3, but it can still be used as an illustration of the proposed identification procedure.

\[
\begin{align*}
\tau, \varphi_m & \quad \tau_s, d \quad \varphi_a \\
J_m & \quad \tau_f \\
J_f & \quad J_a
\end{align*}
\]

Fig. 1. The two-mass flexible model of the robot arm.

The differential equations describing the dynamics of the robot arm are

\[ J_m \ddot{\varphi}_m + rd(\varphi_m - \varphi_a) + \tau_f + \tau_s = \tau \quad (4) \]
\[ J_a \ddot{\varphi}_a - d(\varphi_m - \varphi_a) - \tau_s = 0, \quad (5) \]

where \( J_m \) and \( J_a \) are the moments of inertia of the motor and arm respectively, \( r \) is the gear ratio, \( \tau \) is the motor torque and \( d \) is the damping parameter. The spring and gear friction torques, \( \tau_s \) and \( \tau_f \) respectively, are often approximately modeled by linear models, see e.g., (Ostring et al., 2003). In this work, nonlinear models will be used to capture the effect of the Coulomb friction and to get a more realistic model of the spring. The torque of the spring is modeled as

\[ \tau_s(\varphi_m - \varphi_a) = k_1(\varphi_m - \varphi_a) + k_3(\varphi_m - \varphi_a)^3 \quad (6) \]

where \( \varphi_m \) and \( \varphi_a \) are the angles of the motor and arm respectively, and \( k_1 \) and \( k_3 \) are the parameters of the spring. The torque due to friction is modeled as

\[ \tau_f(\dot{\varphi}_m) = F_v \dot{\varphi}_m + F_c \text{sgn}(\dot{\varphi}_m) \quad (7) \]

where \( F_v \) and \( F_c \) are the viscous and Coulomb friction coefficients. A third nonlinearity of practical importance is the presence of backlash in the gear box, but this problem is left for future work. Using (4) to (7), a nonlinear state space model of the system can be derived. The motor torque, \( \tau \), is used as input signal, \( u \), and with the states defined as

\[ x = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ \dot{x}_1 \\ \dot{x}_2 \\ \dot{x}_3 \end{pmatrix} = \begin{pmatrix} \varphi_m - \varphi_a \\ \dot{\varphi}_m - \varphi_a \end{pmatrix}, \quad (8) \]

the state space equations become

\[ \dot{x}_1 = x_2 - x_3 \quad (9a) \]
\[ \dot{x}_2 = \frac{1}{J_m} \left( -F_v x_2 - F_c \text{sgn}(x_2) \\ -rd(x_2 - x_3) - rk_1 x_1 - r k_3 x_1^3 + u \right) \quad (9b) \]
\[ \dot{x}_3 = \frac{1}{J_a} \left( d(x_2 - x_3) + k_1 x_1 + k_3 x_1^3 \right). \quad (9c) \]

4. IDENTIFICATION PROCEDURE

The aim is to identify all parameters in the robot model, described in Section 3, using experimental data and the nonlinear grey-box identification
procedure described in Section 2. An inherent problem of iterative search routines is that only convergence to a local minimum can be guaranteed. In order to converge to the global minimum, a good initial parameter estimate is important. Therefore a three-step identification procedure is proposed where the first two steps find initial parameter values and in the third step, the nonlinear grey-box identification procedure is applied.

4.1 Step 1: Initial values for rigid body dynamics and friction

There exists a vast amount of literature on the identification of the rigid body dynamics, see, e.g., (Grotjahn et al., 2001; Gautier and Poignet, 2001; Swevers et al., 1997; Pfeiffer and Hölz, 1995). The standard procedure is to use a dynamical model, linear in the parameters, which is characterized by ten inertial parameters per link. This representation is redundant, but there are methods to find a minimal dimensional parameter vector, called base parameters, that characterize the dynamical model. Usually a friction model with two parameters per link is used, describing viscous and Coulomb friction. This model is not sufficient to correctly describe dynamic friction, see (Armstrong-Hélouvry et al., 1994), but compensates the major frictional effects on the identification of rigid body dynamics. The robot is moved along some (optimized) trajectory and applied torque and joint movements are recorded. The parameters are then estimated using linear regression. Since the main interest here is to find initial values, parts of this step could also be replaced by nominal values from CAD models. If, on the other hand, (some) parameters can be estimated with high accuracy in this step, they could be fixed during the third step, leading to a lower dimensional iterative search.

For the robot model in Section 3, the rigid body dynamics and friction is

\[(J_m + \omega^2 J_n)\ddot{\varphi}_m + F_v \dot{\varphi}_m + F_c \text{sgn} \dot{\varphi}_m = \tau \]  

(10)

which can be written as linear regression

\[ (\ddot{\varphi}_m \ \text{sgn} \dot{\varphi}_m) \begin{pmatrix} J_m + \omega^2 J_n \\ F_v \\ F_c \end{pmatrix} = \tau \]  

(11)

4.2 Step 2: Initial values for flexibilities

The major flexibility in an industrial robot is normally located at the joint level, due to the transmission. A two-mass model (or coupled two-mass models for multivariable cases) is then sufficient to describe the dynamics. A trend is to build weaker robot arms, see, e.g., (Albu-Schäffer and Hirzinger, 2001), which also introduces significant flexibilities in the links and their connections. Therefore higher order models are sometimes needed in order to get a sufficient description of the system. Identification of flexibilities is more involved than the identification of rigid body dynamics. The main reason is that now typically only a subset of the state variables are measured and one can therefore not use linear regression. This could of course be solved by adding sensors, see, e.g., (Pfeiffer and Hölz, 1995), where joint parameters are estimated by fixation of the links in fixtures and using force sensors, or (Albu-Schäffer and Hirzinger, 2001), where joint torque sensors are used. These solutions are expensive and the experiments quite involved and therefore not desirable if a simpler solution exists. In (Berglund and Hovland, 2000), a method is described for the identification of masses, springs and dampers, only using applied torque and joint movements. The identification is based on an estimated Frequency Response Function (FRF) in combination with the solution of an inverse eigenvalue problem. See also (Hovland et al., 2001) for an extension to systems containing coupled inertia terms, which is the case for multivariable systems. Here, a similar method will be used to obtain initial values for the flexibilities, see Section 6.2. One could also apply the method proposed in (Isaksson et al., 2003), based on black-box identification.

4.3 Step 3: Nonlinear grey-box identification

Combining the estimates from step 1 and 2 gives an initial parameter estimate, and the nonlinear grey-box identification method described in Section 2 can now be applied.

5. DATA COLLECTION

5.1 Experimental setup

The data used for identification are real data collected from an experimental robot arm. For this kind of application it is necessary to use feedback control while data are collected, both for safety reasons and in order to keep the robot around its operation point. An experimental control system is used, which makes it possible to use off-line computed reference signals for the joint controllers. The identification will therefore be carried out using closed loop data, which might lead to biased estimates, see (Ljung, 1999) for details.
5.2 Excitation signals

For the different steps in the identification procedure, different excitation signals are needed. In step 1, the rigid body dynamics and friction parameters should be excited without introducing any oscillations due to the flexibilities. Therefore a low frequency excitation is preferred. In step 2, on the other hand, the whole frequency band should be excited where notch and peak frequencies in the frequency response function are expected. The influence of static friction should also be reduced, so a broadband excitation with as few zero velocity crossings as possible is selected. Finally, for step 3 a data set (or a combination of data sets) is needed that excite all free parameters in the model.

The properties of the excitation signal will of course affect the quality of the estimated parameters. Since the system is nonlinear, not only the spectrum will matter, but also the amplitude and the actual waveforms. It is common to optimize the excitation signal according to some criterion, see e.g., (Swevers et al., 1997), but that is outside the scope of this paper. The following three excitation signals will be used as reference speed for the controller. They are all sampled at 2 kHz.

- Set 1: Triangle wave signal, 6.25 s of data, with amplitude 40 rad/s and period 5 s.
- Set 2: Multisine signal (sum of sinusoids), 5 s of data, with flat amplitude spectrum in the frequency interval 1-40 Hz with a crest factor of 1.55, period 5 s and a peak value of 5 rad/s. The multisine signal is superimposed on a square wave with amplitude 8 rad/s and period 5 s.
- Set 3: Similar to set 2, but the multisine signal has a peak value of 10 rad/s and the amplitude of the square wave is 12 rad/s.

The last two data sets mainly differ in amplitude and can therefore be used to see nonlinear effects on the estimates. For details on the excitation signals, see, e.g., (Pintelon and Schoukens, 2001; Ljung, 1999).

6. RESULTS

The physical parameters in the robot model from Section 3 will be identified by applying the proposed three-step identification procedure from Section 4, using the experimental data described in Section 5. The gear ratio \( r = 1/224.3 \) is known.

6.1 Step 1

Using data set 1 together with the linear regression (11) gives the following parameter estimates

\[
\begin{bmatrix}
J_m + r^2J_a \\
F_v \\
F_c
\end{bmatrix} = \begin{bmatrix}
0.0280 \\
0.0136 \\
0.642
\end{bmatrix}
\]

The velocity and acceleration used in the regressor, see (11), are obtained from position measurements using non-causal low-pass filtering (filtfilt in Matlab) and central difference algorithms.

6.2 Step 2

The FRFs for data sets 2 and 3 from motor torque to motor acceleration can be seen in Figure 2. Note especially that the notch frequency is higher for the data set with larger amplitude. For a linear system, these estimates should be similar (except for noise). For a linear two-mass system, the approximate transfer function (ignoring the damping, \( d \)) from motor torque to motor acceleration is given by

\[
s(J_a s^2 + k) \\
\frac{s^3J_aJ_m + s^2J_aF_v + s \cdot k(J_m + r^2J_a) + kF_v}{s^3J_aJ_m + s^2J_aF_v + s \cdot k(J_m + r^2J_a) + kF_v}
\]

with \( 1/J_m \) as the high frequency gain and \( \omega_n = \sqrt{k/J_a} \) as the notch frequency. Using the FRFs in Figure 2, the following numerical values are achieved. For data set 2, \( J_m[2] = 0.0126 \) and \( \omega_n[2] = 35.19 \), and for data set 3, \( J_m[3] = 0.0120 \) and \( \omega_n[3] = 37.70 \). The estimate of \( J_m \) is taken as the average value for the two data sets, \( J_m = 0.0123 \). Since the gear ratio, \( r \), is known, an estimate \( J_a = 790 \) is found by combining (12) and \( J_m = 0.0123 \). Knowing \( J_a \), the spring stiffness \( k[i] \) for data set \( i \) is derived by using the approximate relation \( \omega_n[i] = \sqrt{k[i]/J_a} \), which for the two data sets gives \( k[2] = 9.78 \cdot 10^5 \) and \( k[3] = 1.12 \cdot 10^6 \). Since the two amplitudes give different spring constants, it is probably fair to conclude that there is a nonlinear effect present in the experimental data.
The damping is hard to estimate and its initial value is here simply set to zero. For a higher order model, the procedure described in (Hovland et al., 2001) can be used in this step.

To find initial estimates for $k_1$ and $k_3$, the following ad hoc procedure is used. The spring constant $k$ from the FRFs can, in some sense, be regarded as an “average spring constant”. Reasonable estimates for $k_1$ and $k_3$ can then be found by minimizing

$$\sum_{i=2}^{3} \sum_{t=1}^{N} \left( k^{[i]} x_1^{[i]}(t) - k_1 x_1^{[i]}(t) - k_3 x_1^{[i]}(t) \right)^2$$

where $k^{[i]}$ and $x_1^{[i]}(t)$ are the estimated spring constants and spring deflection, respectively, for data sets $i = 2, 3$. Since the state $x_1$ is not measured, it is simulated using the model (9) with the estimated nominal parameters and a linear spring model $\tau_n = k x_1$.

6.3 Step 3

Combining the estimates from steps 1 and 2 gives the initial model $m_0$ in Table 1. To evaluate the quality of estimated models, a measure of the quality of estimated models, a measure of the model fit will be used as

$$\text{fit} = 100 \left( 1 - \frac{\sqrt{\sum_{t=1}^{N} (y(t) - \hat{y}(t))^2}}{\sqrt{\sum_{t=1}^{N} (y(t) - \bar{y})^2}} \right)$$

where $y(t)$ is the measured output (the motor velocity), $\hat{y}(t)$ is the simulated output and $\bar{y}$ is the mean value of the measured output. For the estimation, data set 1 is combined with data sets 2 and/or 3 (using merge in SITB) according to Table 1. Including data set 1 is motivated by the fact that if only data sets 2 and/or 3 are used, the model fit is improved when validating on data sets 2 and 3, but the estimated parameters are unrealistic (e.g., negative Coulomb friction) and the model fit for data set 1 is low. The optimization is carried out for 30 iterations, giving parameter estimates and models shown in Table 1. The estimated models are validated using the three data sets and the model fit is given in Table 2.

Comparing the model fit for the different models in Table 2, one can notice that the model fit is substantially improved by the nonlinear grey-box identification step. However, to be fair, the initial estimates from step 1 and 2 (the m0 model) could probably be improved by using optimal excitation. There are no major differences in model fit when validating with estimation data compared to cross validation. This is also reasonable since the signal-to-noise ratio is quite large. For the m3 model, the relative importance of data set 1 gets lower, which also shows up in the increased model fit for data sets 2 and 3.

To analyze the relative importance on the model fit for each parameter, the estimated model m3 is used and each parameter is perturbed ±20%, one at a time. In Table 3 the difference in model fit can be seen for the three data sets. For data set 1, one can note that the parameters describing the flexibility have a small influence, compared to the rigid body dynamics and friction parameters. The nonlinear stiffness parameter, $k_3$, does not significantly affect the model fit. Removing it gives almost no reduction in model fit. This is a puzzling result, since estimated FRFs (see Figure 2) as well as test bench measurements show an amplitude dependent gear box stiffness. A possible explanation is that the two-mass model is too simple to describe the system and the nonlinear stiffness in the gear box is therefore dominated by linear flexibilities in the robot arm.

In Figure 3 a Bode diagram for the estimated model m3, ignoring the nonlinear model parameters ($k_2$ and $F_c$), can be seen together with the estimated FRFs for data sets 2 and 3. One can clearly see the close correspondence, which further validates the estimated model. However, to capture the two resonance peaks around 60 and 80

Data set 1, one can note that the parameters describing the flexibility have a small influence, compared to the rigid body dynamics and friction parameters. The nonlinear stiffness parameter, $k_3$, does not significantly affect the model fit. Removing it gives almost no reduction in model fit. This is a puzzling result, since estimated FRFs (see Figure 2) as well as test bench measurements show an amplitude dependent gear box stiffness. A possible explanation is that the two-mass model is too simple to describe the system and the nonlinear stiffness in the gear box is therefore dominated by linear flexibilities in the robot arm.

In Figure 3 a Bode diagram for the estimated model m3, ignoring the nonlinear model parameters ($k_2$ and $F_c$), can be seen together with the estimated FRFs for data sets 2 and 3. One can clearly see the close correspondence, which further validates the estimated model. However, to capture the two resonance peaks around 60 and 80
rad/s in the FRF, (at least) a three-mass model would be needed.

7. CONCLUSIONS

A three-step identification procedure has been proposed for the identification of rigid body dynamics, friction, and flexibilities, only using measurements on the motor side. The procedure has been exemplified using real data from an experimental industrial robot together with a flexible two-mass model where nonlinear spring stiffness and Coulomb friction have been added. The estimated physical parameters have realistic numerical values and give a model with high model fit and fairly good correspondence to FRF measurements. However, the nonlinear spring stiffness is not significant in the selected data sets.

There are a number of aspects of the presented results that are subjects for future work. One important problem is to find a model structure that explains the amplitude dependent properties of the system. This will probably involve higher order models as well as additional nonlinearities. A further topic could be to apply the method for a multivariable system. There are no principal problems in the proposed identification procedure, but the last step involving the iterative numerical search would be more time consuming and perhaps numerically sensitive since the system is highly resonant.
