Abstract
In the work presented here, a three-step identification procedure for rigid body
 dynamics, friction, and flexibilities, introduced in (Wernholt and Gunnarsson,
2005), will be utilized and extended. Using the procedure, the parameters can be
identified only using motor measurements. In the first step, rigid body dynamics
and friction will be identified using a separable least squares method, where a
friction model describing the Striebeck effect is used. In the second step, initial
values for flexibilities are obtained using inverse eigenvalue theory. Finally, in
the last step, the remaining parameters of a nonlinear physically parameterized
model are identified directly in the time domain. The procedure is exemplified
using real data from an experimental industrial robot.

1. INTRODUCTION

System identification in robotics is a vast research area and can be divided into, at least, three different
levels or application areas. These levels involve the estimation of the kinematic description, the dynamic
model (often divided into rigid body and flexible body dynamics), and the joint model (e.g., motor inertia,
gearbox elasticity and backlash, motor characteristics, and friction parameters). Some results on the latter
two areas are mentioned in Section 4. An overview of identification in robotics can also be found in
(Kozlowski, 1998).

The work reported here consider nonlinear identification of rigid body dynamics, friction, and flexibilities
using a three-step procedure first introduced in (Wernholt and Gunnarsson, 2005). The procedure is
extended both regarding the friction model, here leading to a pseudo-linear regression, and the example
now have a nonlinear three-mass model. The work is also closely related to the problems considered in, for
example, (Östring et al., 2003; Isaksson et al., 2003). In (Östring et al., 2003), a method is applied where
inertial parameters as well as parameters describing the flexibility of a three-mass model can be identi-
ified directly in the time domain. However, only linear models were considered in their work. (Isaksson et
al., 2003) consider grey-box identification of a two-
mass model with backlash, where black-box modeling
is used to find initial parameter values.

2. NONLINEAR GREY-BOX IDENTIFICATION

The starting point for the nonlinear grey-box identifi-
cation is the continuous-time state space model struc-
ture

\[ \dot{x}(t) = f(t, x(t), \theta, u(t)) \]  \hspace{1cm} (1a)

\[ y(t) = h(t, x(t), \theta, u(t)) + e(t) \]  \hspace{1cm} (1b)

where \( f \) and \( h \) are nonlinear functions, \( x(t) \) is the state vector, \( u(t) \) and \( y(t) \) are input and output signals,
\( e(t) \) a white measurement disturbance signal, and \( t \)
denotes time. Finally \( \theta \) is the vector of unknown
parameters. Given a set of input/output-data the aim
is to determine the parameter vector that minimizes a criterion like

$$V_N(\theta) = \frac{1}{N} \sum_{t=1}^{N} \epsilon^2(t, \theta)$$  \hspace{1cm} (2)$$

where $\epsilon(t)$ denotes the prediction error

$$\epsilon(t, \theta) = y(t) - \hat{y}(t, \theta)$$  \hspace{1cm} (3)$$

The experiments presented in this paper will utilize the nonlinear grey-box model structure NLGREY, available in a beta version of a nonlinear extension to the System Identification Toolbox (SITB), (Ljung, 2003). The model structure NLGREY is similar to the IDGREY model structure in SITB. The model can be either a discrete-time or continuous-time state space model, and it is defined in a Matlab m-file/mex-file. In the current version of the software, only OE-models can be used, i.e. only additive white noise, $\epsilon(t)$, on the output. The prediction $\hat{y}(t|\theta)$ then becomes the simulated output of the model (1) with the input $u(t)$, without $\epsilon(t)$, for the current parameter vector $\theta$. The criterion (2) is minimized by an iterative numerical search algorithm, which involves simulation of the system for different values of $\theta$. The user specifies an initial parameter vector and it is also possible to fix some components in $\theta$. To speed up the numerical optimization, the simulation model is implemented in a mex-file (C-code).

### 3. ROBOT MODEL

The industrial robot that will be studied in this paper is, for movements around an axis not affected by gravity, modeled by a nonlinear three-mass flexible model which is illustrated in Figure 1. Gear ratio $r = 1$ is used in the model, which gives better numerical properties and easier notation. The true physical parameters can later be obtained by a simple scaling with the true gear ratio.

![Fig. 1. The three-mass flexible model of the robot arm.](image)

The input is the torque $\tau$ generated by the electrical motor, while the output is the motor velocity $\dot{q}_m$. The velocities of the other masses, $\dot{q}_g$ and $\dot{q}_a$, are not measurable. Flexibility in the gearbox is modeled by a nonlinear spring, $\tau_f(\cdot)$, between the motor and the second mass. The spring between the second and third mass represents flexibilities in the arm structure. Finally, friction in the system is modeled by nonlinear friction, $\tau_f(\cdot)$, acting on the first mass.

Applying torque balances for the three masses and introducing the states

$$x(t) = \begin{pmatrix} q_m(t) - q_g(t) \\ q_g(t) - q_a(t) \\ \dot{q}_m(t) \\ \dot{q}_g(t) \\ \dot{q}_a(t) \end{pmatrix}$$  \hspace{1cm} (4)$$

gives the nonlinear state-space model

$$\dot{x} = \begin{pmatrix} \frac{1}{J_m} (-\tau_s(x_1) - d_g(x_3 - x_4) - \tau_f(x_3) + u) \\ \frac{1}{J_g} (\tau_s(x_1) + d_g(x_3 - x_4) - k_a x_2 - d_a (x_4 - x_5)) \\ \frac{1}{J_a} (k_a x_2 + d_a (x_4 - x_5)) \end{pmatrix}$$  \hspace{1cm} (5)$$

$$y = x_3$$  \hspace{1cm} (6)$$

where $J_m$, $J_g$, and $J_a$ are the moments of inertia of the motor, gear, and arm respectively, $u = \tau$ is the motor torque, $d_g$ and $d_a$ are damping parameters, and $k_a$ is the stiffness of the second spring. The spring and gear friction torques, $\tau_s$ and $\tau_f$, respectively, are often approximately modeled by linear models (see, for example, (Ostring et al., 2003)). In this work, a nonlinear friction model will be used to capture Coulomb friction and the Striebeck effect as

$$\tau_f(x_3) = F_c x_3 + (F_c + F_{cs} \text{sech}(\alpha x_3)) \tanh(\beta x_3)$$  \hspace{1cm} (7)$$

where $F_c$ and $F_c$ are the viscous and Coulomb friction coefficients, $F_{cs}$ and $\alpha$ are used to model the Striebeck effect, and $\beta$ is used to get a smooth model without discontinuity at zero velocity, which is more suitable for simulation. As a comparison, the simpler friction model

$$\tau_f(x_3) = F_c x_3 + F_c \text{sgn}(x_1)$$  \hspace{1cm} (8)$$

will be used as well. For details on friction modeling, see (Armstrong-Hérouvry et al., 1994). The torque of the spring is modeled as

$$\tau_s(x_1) = k_{g1} x_1 + k_{g3} x_1^3$$  \hspace{1cm} (9)$$

where $k_{g1}$ and $k_{g3}$ are the parameters of the spring.

### 4. IDENTIFICATION PROCEDURE

The aim is to identify all parameters in the robot model, described in Section 3, using experimental data and the nonlinear grey-box identification procedure described in Section 2. An inherent problem of iterative search routines is that only convergence to a local minimum can be guaranteed. In order to converge to the global minimum, a good initial parameter estimate is important. Therefore a three-step identification procedure is proposed. The first step consider identification of rigid body dynamics and friction. In the second step, initial values for flexibilities are obtained. Finally, in the third step the nonlinear grey-box identification procedure is applied.
4.1 Step 1: Rigid body dynamics and friction

There exists a vast amount of literature on the identification of rigid body dynamics, see, for example, (Grotjahn et al., 2001; Gautier and Poignet, 2001; Kożlowski, 1998; Swevers et al., 1997). The standard procedure includes a dynamic model

$$H_b(\dot{q}, \ddot{q}) \theta_b = \tau$$  \hspace{1cm} (10)

which is linear in the rigid body parameters $\theta_b$. Each link gives ten physical parameters. This representation is redundant, but there are methods to find a minimal dimensional parameter vector $\theta_b$, called base parameters, that characterize the dynamic model like

$$H_b(q, \dot{q}) \theta_b = \tau$$  \hspace{1cm} (11)

The base parameters are nonlinear functions of the physical parameters like

$$\theta_b = \phi(\theta_{rb})$$  \hspace{1cm} (12)

In the presence of friction, $\tau$ in (11) should be replaced by $\tau - \tau_f(\dot{q})$. Usually the friction model (8) is used, which gives two additional parameters per link to estimate, but still a linear regression. This model is not sufficient to correctly describe dynamic friction, see (Armstrong-Hélouvry et al., 1994), but compensates the major frictional effects on the identification of rigid body dynamics when using a high amplitude excitation. The robot is moved along some (optimized) trajectory and applied torque and joint movements are recorded. The parameters are then estimated using linear regression.

Here, the more advanced friction model (7) will be used in order to more accurately model the low velocity behavior. For the robot model in Section 3, the rigid body dynamics and friction is

$$(J_m + J_q + J_a) \ddot{q}_m + \tau_f(q_m) = \tau$$ \hspace{1cm} (13)

which can be written as a pseudo-linear regression

$$\dot{\tau}(t|\rho, \eta) = \rho^T \varphi(t, \eta)$$  \hspace{1cm} (14)

where

$$\varphi(t, \eta) = \begin{pmatrix} \ddot{q}_m \\ q_m \\ \text{sech}(\beta q_m) \tanh(\beta q_m) \end{pmatrix}, \hspace{1cm} \rho = (J_F \ F_e \ F_c \ T, \ \eta = (\alpha \ \beta)^T).$$

Here, $J$ is the only base parameter and (12) simplifies to $J = J_m + J_q + J_a$.

Minimizing an identification criterion like

$$V_N(\rho, \eta) = \sum_{t=1}^{N} [\tau(t) - \rho^T \varphi(t, \eta)]^2 = [\tau - \Phi(\eta)\rho]^2$$  \hspace{1cm} (15)

then is a separable least squares problem since the least squares part $\rho$ can be separated out using

$$\hat{\rho} = [\Phi^T(\eta)\Phi(\eta)]^{-1}\Phi^T(\eta)\tau$$  \hspace{1cm} (16)

and the problem is reduced to finding the optimal $\eta$. See (Golub and Pereyra, 1973) for a thorough treatment of this approach.

The result from the first step are estimates of the base parameters $\theta_b$ and the friction parameters $\theta_{fr}$.

4.2 Step 2: Initial values for flexibilities

The major flexibility in an industrial robot is normally located at the joint level, due to the transmission. A two-mass model (or coupled two-mass models for multivariable cases) is then sufficient to describe the dynamics. Weaker (more compliant) robot structures will in addition introduce significant flexibilities in the links and their connections. Therefore higher order models are sometimes needed in order to get a sufficient description of the system. Identification of flexibilities is more involved than the identification of rigid body dynamics. The main reason is that now typically only a subset of the state variables are measured and one can therefore not use linear regression. Many different methods are described in the literature to handle this problem, see for example (Behi and Tesar, 1991; Johansson et al., 2000; Albu-Schäffer and Hirzinger, 2001). They differ in, for example, assumed model structure, required measurement signals, and complexity of the identification method.

Here, a method described in (Berglund and Hovland, 2000) will be used for the identification of masses, springs and dampers, only using applied torque and joint movements. The identification is based on an estimated Frequency Response Function (FRF) together with the solution of an inverse eigenvalue problem. Consider an Nth order spring-mass system, which can be modeled as

$$M \ddot{q} + Kq = \tau$$  \hspace{1cm} (17)

where $M$ is a diagonal inertia matrix, $q = (q_1 \ldots q_N)^T$ is a vector of the position of the masses, and $K$ is a tridiagonal matrix built up from the $N - 1$ spring constants. The eigenvalues of the system are given by

$$Bu = \lambda u$$  \hspace{1cm} (18)

where $B = L^{-1}KL^{-T}$, $u = L^Tq$, and $L = M^{1/2}$. Using the FRF gives information about the resonance frequencies and anti-resonance frequencies. The first eigenvector $u_1$ of $B$ can be derived from these frequencies, assuming that the damping is neglectable. The $B$ matrix can then be computed recursively by the Lanczos algorithm using $u_1$ and the squared resonance frequencies. Finally, the elements of $M$ and $K$ can be reconstructed by using their special structure. A damping matrix can be estimated afterwards by minimizing the distance between the FRF and the model at the resonance and anti-resonance frequencies, using some optimization routine. For details about the method, see (Berglund and Hovland, 2000) and the references therein.
The result from the second step gives initial estimates of (some) rigid body parameters, \( \hat{\theta}_b \), and parameters describing the flexibilities, \( \theta_{fr} \), typically springs and dampers. As an optional step, one could of course refine all these estimated parameters by curve fitting between the FRF and the model as well.

4.3 Step 3: Nonlinear grey-box identification

Combining the estimates from step 1 and 2 gives an initial parameter estimate, and the nonlinear grey-box identification method described in Section 2 can now be applied. To reduce the complexity, parameters estimated with high accuracy in the previous steps can be fixed in this step, leading to a lower dimensional iterative search. Keeping \( \hat{\theta}_b \) and \( \theta_{fr} \) from step 1 fixed will result in a modified criterion

\[
\min_{\theta} V_N(\theta) = \frac{1}{N} \sum_{i=1}^{N} e^2(t, \theta) \quad (19)
\]

subject to \( \phi(\hat{\theta}_b) - \hat{\theta}_b = 0 \) \( (20) \)

\( \theta_{fr} - \hat{\theta}_{fr} = 0 \) \( (21) \)

where \( \theta = (\hat{\theta}_b^T, \hat{\theta}_{fr}^T, \hat{\theta}_{fr1}^T)^T \).

5. DATA COLLECTION

The data used for identification are real data collected from an experimental robot. For this kind of application it is necessary to use feedback control while data are collected, both for safety reasons and in order to keep the robot around its operation point. An experimental control system is used, which makes it possible to use off-line computed reference signals for the joint controllers.

For the different steps in the identification procedure, different excitation signals are needed. In step 1, the rigid body dynamics and friction parameters should be excited without introducing any oscillations due to the flexibilities. Therefore a low frequency excitation is preferred. In step 2, on the other hand, the whole frequency band should be excited where notch and peak frequencies in the frequency response function are expected. Since FRF estimates are based on an assumption of linearity, the influence of nonlinear friction should be reduced, so a broadband excitation with as few zero velocity crossings as possible is selected. Finally, for step 3 a data set (or a combination of data sets) is needed that excite all free parameters in the model. The following periodic excitation signals will be used as reference speed, \( q_{ref} \), for the controller. They all have a period time of 10 s and one period the steady state response is collected, sampled at 2 kHz (\( T = 0.5 \text{ ms} \)).

**Data set 1:** Multisine signal (sum of sinusoids) with frequencies 0.1, 0.3, and 0.5 Hz. Five different peak values have been applied: 1, 5, 20, 40, and 160 rad/s.

**Table 1.** Estimated parameters from step 1, including one standard deviation.

**Data set 2:** Multisine signal with a flat amplitude spectrum in the frequency interval 1-40 Hz with a peak value of 16 rad/s. The multisine signal is superimposed on a filtered square wave with amplitude 20 rad/s and cut-off frequency 1 Hz.

**Data set 3:** Similar to data set 2, but without the square wave.

For details on the selection of excitation signals, see, e.g. (Pintelon and Schoukens, 2001; Ljung, 1999).

6. RESULTS

The physical parameters in the robot model from Section 3 will here be identified by applying the proposed three-step identification procedure from Section 4, using the experimental data described in Section 5.

6.1 Step 1

Using data set 1, with one period of data for each of the five amplitudes, together with the separable least squares method, as described in Section 4.1, gives parameter estimates according to Table 1.

As can be seen, some of the friction parameters have a quite large standard deviation, which actually indicates that the model cannot fully describe the data sets used for identification. The parameters in the right column only affect the low velocity region, and in this region the five data sets with different amplitudes behave quite differently (for example smaller \( \beta \) for larger amplitudes). An even more advanced friction model which handles these differences is therefore needed in order to fully capture the friction dynamics.

The separable least squares problem has no local minima in the area of interest, as can be seen in Figure 2. The loss function (2) is also relatively insensitive to different values of the two parameters since such differences can be somewhat compensated by the \( F_{cs} \) parameter.

To see the differences, two simpler friction models are used as well, where first \( F_{cs} \) (and \( \alpha \)) are set to zero (3 parameter model), and secondly using (8) (2
Section 6.2 Step 2

In this step, first the FRF must be estimated. Before the estimation, the input signal should be modified according to the estimated friction model from step 1. This gives minor differences for data set 2, but for data set 3 the resonances get more visible. The FRF for data set 2 from motor torque to motor acceleration can be seen in Figure 4 on the next page.

Solving the inverse eigenvalue problem according to Section 4.2 gives initial estimates of \( \theta_{vb} = (J_1 \ J_2 \ J_3)^T \) and \( \theta_{fi} = (k_{g1} \ k_{g3} \ \alpha \ \beta \ dm \ da)^T \), except for \( k_{g3} \) which is kept zero at this step due to the assumption about linearity. These values can be seen in Table 3, model \( m5_{init} \).

6.3 Step 3

Combining the estimates from steps 1 and 2 gives the initial model \( m5_{init} \) in Table 3. The nonlinear grey-box identification according to Section 4.3 is then applied, using data set 2. First, \( k_{g3} = 0 \) is used, giving the model \( m5 \). Releasing \( k_{g3} \) gives the model \( m5_{gk3} \). For comparison, models are also estimated using the simpler friction models from Section 6.1, giving models \( m3 \) and \( m2 \), where the number indicates the number of friction parameters. The rigid body parameters, \( \theta_{rb}, \) and the second damper are estimated with a standard deviation less than 10%. For the remaining parameters in \( \theta_{fi}, \) the standard deviation is less than 2%.

To validate the estimated models, four additional realizations of the multisine signal have been applied, both for data set 2 and 3. The loss function for each of the models in Table 3, including the rigid model from step 1 have then been calculated for each of the realizations. Their values have first been normalized by the loss using the rigid model, and secondly averaged over the realizations to get the average loss, shown in Table 4. Comparing \( m5_{init} \) and \( m5 \) shows the big improvement by using step 3 in the procedure. For data set 2, the more advanced friction model (7) reduce the loss function, compared to using (8). For data set 3, on the other hand, there are no major differences.

result. The nonlinear spring stiffness reduces the loss function, as can be seen by comparing the loss for \( m_5 \) and \( m_5 k_3 \). Using a data set with a different amplitude would probably show an even bigger difference.

The discontinuous friction model (8) gives problems in simulation and therefore a large \( \beta \) value is used instead. This is actually another reason for using the more advanced friction model (7), besides that it gives better performance.

Finally, a Bode diagram of the estimated model \( m_5 \) can be seen in Figure 4 together with \( m_5 \text{init} \) and the estimated FRF for data set 2.

7. CONCLUSIONS

A three-step identification procedure has been used for the identification of rigid body dynamics, friction, and flexibilities, only using measurements on the motor side. The procedure has been exemplified using experimental data from an industrial robot together with a flexible three-mass model where nonlinear spring stiffness and a nonlinear friction model have been added. The estimated physical parameters have realistic numerical values and give a model with good correspondence to FRF measurements.

To further improve the results the friction could be modeled even more accurately. The method will also be applied to a multivariable system.

Nonlinear Identification of a Physically Parameterized Robot Model

Abstract

In the work presented here, a three-step identification procedure for rigid body dynamics, friction, and flexibilities, introduced in (Wernholt and Gunnarsson, 2005), will be utilized and extended. Using the procedure, the parameters can be identified only using motor measurements. In the first step, rigid body dynamics and friction will be identified using a separable least squares method, where a friction model describing the Striebeck effect is used. In the second step, initial values for flexibilities are obtained using inverse eigenvalue theory. Finally, in the last step, the remaining parameters of a nonlinear physically parameterized model are identified directly in the time domain. The procedure is exemplified using real data from an experimental industrial robot.
