Abstract

Upon annealing cold-pressed Ti2AlC, -325 mesh powders, at 1500 °C for 8 h in argon, the resulting partially sintered sample contained 43(±2) wt.% of the layered ternary carbide Ti5Al2C3. Herein, the X-ray powder diffraction pattern of Ti5Al2C3 is reported for the first time. Its structure and stoichiometry are confirmed through high-resolution transmission electron microscopy. This phase has a trigonal structure (space group P3) with a unit cell consisting of 3 formula units and cell parameters of a = 3.064 Å, c = 48.23 Å. The lattice parameters determined through first principles calculations agree reasonably well with the experimentally determined values. At 147.1 GPa, the calculated bulk modulus falls between the bulk moduli of the MAX phases Ti2AlC and Ti3AlC2. The transformation from Ti2AlC to Ti5Al2C3 is topotactic.

1. Introduction

Binary, early transition metal carbides possess a number of desirable properties including high-temperature stability, high melting point, high hardness, and low compressibility relative to metals; however, their applications are limited because they are brittle, difficult to machine, and highly susceptible to thermal shock. The Ti-Al-C system includes ternary phases that possess ceramic-like properties of their binary relative, TiC, while overcoming many shortcomings of the latter by acquiring some of the more favorable properties of metals. Most notably, two of the ternaries in the system are part of a family of nanolaminated compounds known as MAX phases, which have the general formula Mn+1AXn (n = 1-3) where M is an early transition metal, A is an element from groups IIIA or IVA, and X is C or N. They can be further characterized according to their value of n: “211” for n = 1, “312” for n = 2, and “413” for n = 3.
The synthesis of Ti2AlC was first reported in the 1960s [1], along with other 312 phases, including Ti3SiC2 [2]. Several decades later in 1994, Pietzka and Schuster synthesized Ti3AlC2, for the first time, and found that it was isostructural with Ti3SiC2 [3]. It was later discovered that, as a class, the MAX phases have unusual yet attractive and sometimes unique combinations of properties, and these phases have since attracted a great deal of interest [4-7]. They are excellent electric and thermal conductors with exceptional thermal shock resistance. While they are elastically quite stiff, they are also relatively soft and readily machinable, with exceptional damage tolerance [4, 5, 8]. Some are creep and fatigue resistant [9-11]. Of the > 60 MAX phases known to date, Ti2AlC and Ti3AlC2 are particularly significant when considering the transition of MAX phases from the laboratory to practical applications. They have perhaps the greatest potential for commercialization due to their excellent oxidation resistance and the accessibility of their starting materials, which are relatively inexpensive and readily available [12, 13].

In the Ti-Al-C system, three ternary compounds have been reported to date. Two of them are the MAX phases Ti3AlC2 and Ti2AlC, which crystallize in a hexagonal lattice (space group P63/mmc) composed of M-X octahedra stacked between layers of the A element. Another ternary carbide, Ti3AIc, has a structure similar to oxide perovskites, with Ti and Al forming an FCC-like structure and C in the body-centered octahedral hole [14, 15].

Since Ti2AlC and Ti3AlC2 are some of the more promising MAX phases for industrial and commercial uses, the ability to fine-tune their stoichiometry and crystal structure (for example, by altering their stacking sequences) would open more opportunities for engineering their properties. In the present study, we report on the synthesis of a new MAX phase, Ti5Al2C3. Its stacking sequence can be considered as alternate layers of Ti2AlC and Ti3AlC2. This phase has previously been reported by Lin et al in Ti2AlC bulk samples [16] and by Wilhelmsson et al in Ti2AlC thin films [17]. In both cases, however, it was found in samples that were predominately single-phase Ti2AlC. In other words, it was only observed in small domains through transmission electron microscope, TEM, analysis. Consequently, its X-ray diffraction, XRD, patterns are unknown.

Herein, we show that Ti5Al2C3 can be synthesized in bulk. We determine its long-range crystal structure, stacking, and stoichiometry through XRD and TEM analysis. We also perform first principles calculations to determine its ground state parameters and its electronic structure.

2. Experimental Details

The sample was made by heating Ti2AlC powders that were commercially obtained (3-ONE-2, Voorhees, NJ, > 92 wt.% purity; particle size < 44 µm, i.e., -325 mesh) in an alumina tube furnace under flowing argon, Ar, at 10 °C/min to 1500 °C. The powders were then held at temperature for 8 h. After cooling to room temperature, powders were obtained from the resultant partially sintered bulk piece (relative density of ≈ 80%) using a titanium nitride coated milling bit.

XRD patterns were obtained with a powder diffractometer (Rigaku Smartlab, Japan) using Cu Kα radiation and a step scan of 0.02°, with 1 s per step. Si powder was added to some samples as an internal standard to calibrate the diffraction angles and the instrumental peak broadening. Rietveld analysis was performed using Material Analysis by Diffraction/Reflectivity (MAUD) software [18, 19],
assuming the presence of Ti2AlC, Ti3AlC2, Si (used as an internal standard) and a proposed phase Ti5Al2C3 (Fig. 3a). The phase fractions, background, lattice parameters (except for Si), thermal factors, and symmetry-constrained atomic positions were refined using the least-squares refinement implemented in MAUD.

Samples for TEM observation were collected by a holey carbon grid after suspending the powder in ethanol. The TEM used (FEI Tecnai G2 TF 20 UT) had a 0.19 nm point resolution and 200 kV working voltage. The crystal structure of the new phase was investigated by selected electron diffraction (SAED) and high resolution TEM (HRTEM), together with image simulation.

Ab initio calculations, based on density functional theory (DFT), were performed using the Perdew-Burke-Eruzerhof (PBE) generalized gradient approximation (GGA) [20] with a plane wave cutoff of 400 eV. The total energy was converged to < 0.02 meV/atom with a 13x13x2 Γ-centered k-point grid, as implemented in the VASP software. For Ti, the semi-core 3p states were treated as valence electrons. Computations of the electronic properties and structural parameters were carried with calculations of the total density of states (DOS) and energy minimization through the relaxation of atomic positions and c/a ratio for a range of fixed volumes. The equilibrium volume and bulk moduli were obtained with the modified Morse equation of state fit of the total energy as a function of volume. [21]

3. Results and Discussion

The XRD pattern of the Ti2AlC powder sample before and after heat treatment is shown in Figs. 1a and 1b, respectively. Before heat treatment (Fig. 1a), the sample was predominantly single phase Ti2AlC (red diamond markers), with a small amount (~9 wt.%) of Ti3AlC2 (gray crosses). After heat treatment (Fig. 1b), additional peaks appeared corresponding to the additional phase we identified as Ti5Al2C3 (blue circles). The peaks at 2θ = 5.6°, 11.0° and 16.5° correspond to the (0003), (0006) and (0009) peaks for Ti5Al2C3, respectively. From these distinct peaks that cannot be accounted for by Ti2AlC or Ti3AlC2, it is readily apparent that the sample contains a substantial amount of this new phase.

To emphasize and confirm the assignment of the (000l) peaks, we collected patterns from discs produced by cold pressing, CPing, the heat-treated powders at loads corresponding to a stress of ≈ 1 GPa. The inset of Fig. 1 shows the 2θ = 5 - 20° region of the XRD pattern from (i) the powder sample, and (ii) the cold-pressed sample. The two patterns are normalized to the (111) peak for Si at 2θ=28.5° (not shown). The (0003), (0006), and (0009) peaks of Ti5Al2C3 are labeled, and their positions are marked by blue circles. A clear increase in the intensity of these peaks and not others with CPing confirms assigning these peaks to the 000l. The MAX phases are layered and cold pressing orients the basal planes parallel to the loading direction. Note that the peak at 13.0° is the (0002) peak of Ti2AlC, which is also expected to increase with CPing due to preferred orientation.

Table 2 compares the XRD results obtained experimentally and calculated peaks. Out of the 320 calculated peaks, only those with relative intensities greater than 1 are shown. Rietveld refinement with MAUD gave 43(±2) wt.% Ti5Al2C3 for the sample after heat treatment, with 49(±2) wt.% Ti2AlC, and 7(±2) wt. % Ti3AlC2. The lattice parameters of Ti5Al2C3 are \(a = 3.064(2) \text{ Å}, c = 48.23(2) \text{ Å}\) and its space group is P3 (143).
Fig. 1: XRD patterns of Ti2AlC powder sample, (a) as received and (b) after heat treatment. Inset shows region between 2θ = 5° and 20° for the sample after heat treatment, indexing the (0 0 0 3), (0 0 0 6) and (0 0 0 9) peaks for Ti5Al2C3: (i) sample in powder form, and (ii) cold-pressed pellet, where both patterns are normalized to the Si peak at 2θ = 28.5° (not shown). Markers show peak positions for Si (green squares), Ti2AlC (red diamonds), Ti5Al2C3 (blue circles), and Ti3AlC2 (gray crosses). XRD patterns are shifted to accommodate markers.

The structure was confirmed by HRTEM (Fig. 2), where there are alternate layers containing 2 and 3 Ti layers sandwiched between Al layers, with C filling the octahedral sites in between Ti layers, in agreement with the simulated image of the [11 0] zone axis projection. The space group of this phase is different from those of Ti3AlC2 and Ti2AlC due to the break in symmetry caused by the alternating stacking sequence. This structure has the same stacking sequence observed in the TEM in Ref. [17].

The HRTEM image is also consistent with the equilibrium structure from first principles calculations. The full structure is shown in Fig. 3a, compared to that of Ti3AlC2 (Fig. 3b) and Ti2AlC (Fig. 3c). The stacking sequence for the Ti and Al atoms are shown next to the structures. A unit cell of Ti5Al2C3 consists of three formula units with a total of 6 Al layers, where every other region between the Al layers is filled with one Ti-C octahedra, as seen in Ti2AlC, and rest contain two Ti-C octahedra, as in
Ti3AlC2. In order to accommodate this structure, the stacking sequence of the Al layer must shift every two layers.

Figure 3d shows the volume vs. energy plot determined by first principle calculations, as well as the equation of state fits. The bulk modulus, B0, determined through the fit is the highest for Ti3AlC2, which is apparent in Fig. 3d from its higher curvature. The bulk moduli for Ti2AlC, Ti3AlC2, and Ti5Al2C3 are listed in Table 1, where B0 varies in the order Ti2AlC < Ti5Al2C3 < Ti3AlC2. The lattice parameters determined by first principles calculations agree well with the experimental values from XRD and TEM (Table 1).

The calculated electronic density of states is shown in Fig. 4, where 0 corresponds to the Fermi level. The density of states is quite similar to that of Ti2AlC and Ti3AlC2 [22-24], where its conductivity is predominantly due to the Ti d orbitals. Since the stoichiometry is 2.5:1:1.5 (effectively that of a MAX phase with n = 1.5), it should be expected to have electronic properties that fall somewhere between Ti2AlC and Ti3AlC2.
Fig. 3: Crystal structure and stacking sequence of (a) Ti$_5$Al$_2$C$_3$, (b) Ti$_3$AlC$_2$, and (c) Ti$_2$AlC. (d) Volume vs. energy plot for the three structures in (a)-(c), showing values determined from first principles calculations (solid data points) and the MO88 equation of state fit (lines).
Since both Ti2AlC and Ti3AlC2 are generally synthesized at temperatures between 800 and 1500 oC [13, 25-28], the phase produced through heat treatment is highly dependent on the ratio of the starting powders. In the sample investigated in this study, we found regions where Ti5Al2C3 was present in the same grain as Ti3AlC2 (Fig. 5). It is therefore reasonable to assume that the formation
of Ti5Al2C3 is topotactic, most likely occurring through outward diffusion of Al and the re-ordering of TiC octahedra in Ti2AlC. A phenomenon that could help explain the formation of Ti5Al2C3 is a so-called gradient structure, reported in a hot-pressed study of the Ti-AL-C system by Mei et al [29]. In that study, various compositions of Ti, Al, and C powders were hot pressed at 1500 oC for 60 minutes under 30 MPa. It was found that the samples contained an inhomogeneous structure throughout their volumes, where most of the phases were Al-deficient. Moreover, the Ti content was constant along the axial direction, whereas the Al distribution increased continuously from the hot pressed surface to the center of the sample. As a result, the relative volumes of TiC, Ti3AlC2, and Ti2AlC varied gradually. The evaporation of Al was considered a fundamental reason for such a formation, since Al has a higher vapor pressure than Ti at 1500 oC [30].

Fig. 5: HRTEM image of a grain containing both Ti5Al2C3 and Ti3AlC2 showing (a) lower-resolution and (b) higher-resolution TEM micrographs with respective unit cells indicated (the interface between the two phases is indicated by an arrow in (a)) with corresponding SAED patterns from the Ti5Al2C3 (“523”) and Ti3AlC2 (“312”) regions shown above and below figure (a), respectively.

Here, we postulate that the evaporation of Al from Ti2AlC results in a higher Ti:Al ratio, causing Ti5Al2C3 to be more thermodynamically favorable. It is reasonable to assume that further heating would convert Ti5Al2C3 to Ti3AlC2 and ultimately to TiCx.
The results presented herein provide evidence for Ti5Al2C3 – with a stacking sequence combining that of Ti3AlC2 and Ti2AlC and properties similar to the two phases – that exists in bulk, formed when Ti2AlC powders are heated to 1500 °C for 8 h. Work to explore the effect of annealing times and temperatures on the microstructure and atomic ordering of ternary phases in the Ti-Al-C system would be needed to understand the kinetics and mechanisms for the formation of the Ti5Al2C3 phase.

Conclusions

A ternary phase, Ti5Al2C3, was synthesized in bulk form for the first time by heating Ti2AlC under Ar for 8 h at 1500 °C. The transition from Ti2AlC to Ti5Al2C3 is topotactic. The crystal structure of Ti5Al2C3 was found to be trigonal (P3), with a and c parameters of 3.067 Å, 48.16 Å, respectively. The stacking of atomic layers in Ti5Al2C3 can be considered as a combination of that in Ti2AlC and Ti3AlC2.
